THE PRINCIPLES AND PRACTICE OF VETERINARY MEDICINE.
BRONCHO-PNEUMONIA, or so-called American Contagious Pleuro-Pneumonia.
THE
PRINCIPLES AND PRACTICE
OF
VETERINARY MEDICINE.

BY
WILLIAM WILLIAMS,
F.R.C.V.S., F.R.S.E., ETC.

FOURTH EDITION.

JOHN MENZIES & CO., EDINBURGH AND GLASGOW.
J. & A. CHURCHILL, LONDON.

1884
TO

MAJOR-GENERAL SIR F. W. J. FITZWYGRAM, BART.,

THIS WORK IS RESPECTFULLY DEDICATED,

IN

RECOGNITION OF MANY KINDNESSES,

BY

THE AUTHOR.
PREFACE TO THE FOURTH EDITION.

The rapid absorption of the third edition of this work again imposes upon the Author, after an interval of only two years, the duty of preparing another edition; and owing to the great advances and the striking discoveries, many additions and revisions have had to be made.

The chapters on Anthrax, Septicaemia, and those portions dealing with the Germ Theory, have been entirely recast and brought up to date, whilst many new illustrations have been added, most notably—through the kindness of J. H. B. Hallen, Esq., M.R.C.V.S., F.R.S.E., F.R.C.P.E., and President of the Cattle Plague Commission in India—those illustrating the Pathological changes seen in Cattle Plague as it occurs in India, where it seems the post-mortem lesions are more pronounced than those seen in this country.

The chapters on Parasites have again been carefully revised, and some new facts brought forward in connection with Parasitic Diseases, and at least one more important disease added to those already known to arise from this cause. I allude to that induced by the Strongylus contortus, which is now described, in the English language at least, for the first time, and its importance duly considered.

The Author has again to express his thanks for much valuable and kindly assistance rendered by his colleagues, Professors Lewis, Hunter, and W. O. Williams.

New Veterinary College,
Edinburgh, November 1884.
PREFACE TO THE THIRD EDITION.

The continued success of this work has, after an interval of only three years, again imposed on the Author the agreeable duty and responsibility of preparing another edition. That the object for which it was originally written,—viz., to give an impetus to the study of Veterinary Science, and to enable it to take its proper place in the sphere of Medicine,—is being gradually accomplished, is evidenced by the demand for this and similar works in the United States and throughout the Colonies, as well as at home.

While making a careful revision of the text, it has also been found necessary, in order to keep pace with the rapid advance of Medical Science, to re-cast some portions and make considerable additions to others. The chapters on Parasites, originally written by Dr. Corbould, have been almost entirely re-cast; and in carrying out this special work the Author has been ably assisted by his colleague Mr. A. N. McAlpine, B.Sc., Professor of Natural History and Botany at the New Veterinary College, as also in the drawings illustrating the configuration and development of various Parasites, of which six plates, with explanatory descriptions, have been added.

The recent successful experiments in inoculation by Pasteur and others, which were so graphically explained at the International Medical Congress in London in 1881, mark a new departure in the field of Medical Science, in its application to various diseases; as also the successful demonstration of the Germ Theory of Koch in Septicaemia, Tuberculosis, &c. The Author has had his attention closely directed to these theories and their demonstration, and their discussion forms part of the Supplement which he has found it necessary to add to this work in recording the most recent discoveries and observations in Pathology.
A series of original experiments have for some time been conducted by the Author on the causes and nature of a hitherto mysterious and most destructive disease amongst Sheep, namely, "Louping-ill;" as the result of which he believes he has been successful in discovering the existence of an organism which may reasonably be considered as the cause of the disease. Assisted by his colleagues, Dr. Hunter, Professor of Physiology, Mr. Lewis, Professor of Anatomy, and his son, Mr. W. O. Williams, Demonstrator of Practical Pathology, who for many months patiently and cheerfully helped him with the experiments, many hundreds of observations and cultivations of the organism were made, and the conclusions deducible therefrom viewed from every standpoint, with the ultimate results given in the Supplement. Dr. Hunter also made the microscopic drawings of the Bacillus Chorea Ovis.

An entirely new disease has been discovered in Sheep, viz., Lipæmia, or Fatty Blood, observations on which will also be found in the Supplement.

All these investigations and discoveries are not only of much general interest, but are also of the greatest importance to the Profession in their direct bearing on the food supply of the country. The preservation of health, and the prevention of disease, local or epizootic, among our Domesticated Animals, has become as much a national question as that of the population itself, and will yet come to occupy that attention from the Legislature due to its importance. In connection with this subject, the Author has to remark that, with reference to the so-called Pleuro-Pneumonia among American Cattle, he has seen no reason to modify his views, first given in the last edition of this work; the Government of the United States having, through Dr. Lyman and others, made an exhaustive examination of the whole question, and issued a Report which proves that no Contagious Pleuro-Pneumonia exists, or has existed, in those districts from whence Cattle are imported into this country.

W. W.

New Veterinary College,
Kolnburg, 1st September 1882.
PREFACE TO THE FIRST EDITION.

This work is intended to be a companion to that on the *Principles and Practice of Veterinary Surgery*, published two years ago, and of which a second edition has been called for, and is about to be issued.

The first portion is devoted to a brief elucidation of General Pathology, as applied to the Domesticated Animals, and the second to a description of Special Diseases other than Surgical. An endeavour has been made in the following pages to arrive at a scientific classification, by the arrangement of Diseases under two heads, namely, Contagious Diseases and Non-Contagious. Much difficulty has been experienced by the Author in satisfactorily arranging Non-Contagious Diseases, as in many instances the causes are still obscure. But so far as modern science and experience have enabled him, he has arranged and classified almost all the Diseases with reference to their causes, especially when these have been ascertainable. Stress has been laid on the nature of the various Diseases, with the special view of encouraging a rational mode of treatment.

In the preparation of this work the Author has, in addition to his own resources, had the assistance of others who have made
particular branches their special study. Where he has availed himself of such assistance, it has been duly acknowledged; but, in addition, he cannot omit specially to thank Dr. Coubold for his paper on Parasites; Mr. C. Lyman, V.S., Boston, U.S., for an account of Cerebro-Spinal Meningitis as it presents itself in America; Mr. James Anderson, V.S., Glasgow, for his translation of the Chapters on Charbon; Mr. Archibald Robinson, V.S., Greenock, for his paper on Maladie du Coit; and to Professor Vaughn for his excellent Drawings and other valuable help.

The Author would, in conclusion, express the hope that this work, prepared in the face of grave obstacles, may meet with acceptance by his professional brethren, and others interested in the advancement of Veterinary Science.

W. W.

THE
PRINCIPLES AND PRACTICE
OF
VETERINARY MEDICINE.

CHAPTER I.
INTRODUCTORY.

The external diseases incidental to the domesticated animals having been discussed in my work on Veterinary Surgery, I purpose in the present volume to enter into a consideration of the more purely medical or internal ailments from which our patients are liable to suffer.

I have advisedly made a distinction between Veterinary Medicine and Veterinary Surgery, not only for the reason that the subjects, thus divided, are more easily dealt with, but because conclusions which may be considered almost hypothetical and speculative in medicine, are replaced in surgery by the tangible and demonstrable.

Medicine is studied as a science and as an art: as a science, when it inquires into all the circumstances under which diseases become developed, the condition of their existence, and into their nature and causes; as an art, when it is directed towards the recognition, the prevention, and cure of diseases. In fact it is the art of understanding the nature of diseases, so far as to appreciate their causes, to prevent their occurrence when possible, and to promote their cure or to relieve them when they occur.—(Biglow. Aitken.)

In order that the student be enabled to comprehend Medicine as a science, and its application as an art, it is necessary be
should understand Pathology, which, in its full and proper meaning, implies a knowledge of diseased processes, abnormal conditions, and morbid structures, as well as what precedes them and what results from them. For this purpose a knowledge of many collateral branches of science is essential, more particularly a knowledge of Physiology; and no one can be a physiologist without being an anatomist and a chemist. By Physiology is meant that science which treats of the conditions, phenomena, and laws of life whilst the animal body is in a state of health. Without a knowledge of the laws of health, it is impossible to grasp and comprehend the laws of disease, for it may be truly said that the latter are but perversions of the former, and are natural, or physiological, under the operation of existing circumstances and causes.

In addition to Pathology and Physiology, Medicine comprehends Therapeutics, or the science which explains the actions of remedies upon the animal body, the means by which disease may be naturally overcome, and a return to health assisted and promoted; and Hygiene or Prophylaxis, which treats of the sanitary condition, food, and surroundings whereby disease may be prevented, and all other methods by which health may be preserved.

Disease may also be studied clinically: that is to say, disease may be studied as it presents itself in each particular case to the attention of the observer. The term clinic can scarcely, with propriety, be applied to any method by which diseases of the lower animals are studied, as it means "a patient who keeps his bed," but for the want of a better, and as it is now a generic term, I am constrained to retain it.

Before proceeding further with our object, it is necessary that I endeavour to give a definition of disease, and this I can only do by following the rules already laid down by our latest pathologists. A definition of disease can only be arrived at by comparing it with the standard of health, and health, says Williams, "consists in a natural and proper condition and proportion in the functions and structures of the several parts of which the body is composed;" but no fixed rule can be applied to this, for what is health in one may be disease in another, and there are degrees or gradations of health which cannot be said to be due to disorder or disease. For example, one animal may fatten and maintain the most robust health upon the same
quantity of food that would keep another thin and poor. "In
plain words, health does not signify any fixed and immutable
conditions of the body, nor does health necessarily imply the
integrity of all the bodily organs: it is not incompatible with
great and permanent alterations, nor even with the loss of parts,
that are not vital. Our comprehension of health being thus
indefinite, our idea of disease must be indefinite also; and the
best definition that can be given of it is, that it is a deviation
from the state of health, consisting generally in a change in the
properties or structure of any tissue or organ, which renders
such tissue or organ inadequate to the performance of its healthy
actions and functions."—(Watson.)

It must not, however, be supposed that disease, as exhibited
by an unnatural or morbid condition, and by phenomena which
are seemingly abnormal, is unnatural in itself; for in reality
disease may be looked upon as the natural expression of a com-
bination of conditions, the essential and proper consequences
of some cause or influence which has acted, or is acting, upon
the animal body. To adduce a familiar example, let us suppose
a blister is applied to the skin: the inflammation of the skin
which is thus produced is certainly unnatural, and may with
propriety be called disease; but if we look further into the matter,
we can easily understand that the inflammation, vesication, or
even ulceration so induced are the natural results of the action
of the irritant,—in fact, the proper and healthy reaction of a
healthy organism to the irritation of the blister. The absence
of this reaction—the skin remaining healthy—under such con-
ditions would indeed be unnatural, unlooked for, and incompre-
hensible. This may be taken as a type of cause and effect in all
diseases: it is not the inflamed condition of the skin, nor even
the constitutional disturbance which may be caused by a severe
blister, but the presence of the blister that is really unnatural.
This illustration, homely as it may seem, is important, as all
real advancement in prevention and treatment is based upon
a due appreciation of the causes of disease; for in the past,
more particularly in Veterinary Medicine, the aim and purpose
of practice has been directed to the treatment of symptoms—to
deal with effect, often ignoring the cause. Hence the many
systems, founded on erroneous bases, by which diseases have
been combated, have been productive of much harm.
CHAPTER II.

PATHOLOGY.

Pathology, or more properly, when applied to the lower animals, Zoö-Pathology, is derived from the Greek words Παθος, a disease, and Διαγνωσis, a discourse—the doctrine of disease; and is divided into General and Special Pathology.

General Pathology includes—1st. Etiology, or a knowledge of the causes of disease: 2d. Semiology or Symptomatology, or a knowledge of the morbid phenomena or symptoms by which disease is manifested: 3d. Pathogeneity, which deals with the seats or localities of disease: 4th. Nomenclature—its division and classification: 5th. Diagnosis—the methods by which it is detected—its distinction: 6th. Prognosis—its probable results; and Morbid Anatomy, including Histology—the method by which the morbid alterations of structure and the elementary constituents of diseased products are discovered.

Etiology. The cause of disease, or, in other words, the circumstances which precede it, and to which its occurrence is due, are arranged under three heads, namely—the predisposing, the exciting, and the proximate.

The term proximate is used to represent the pathological condition or essential bodily change on which the symptoms of disease depend; in fact, the proximate cause has been stated to be the disease itself, and for this reason some writers have expunged the term, and have been content to arrange the causes of disease under the heads predisposing and exciting. Later writers, however, have revived the term, and Dr. Bristowe gives the following illustration: "A woman who has been frequently exposed to the contagion of scarlet fever without taking the disease, becomes at the period of childbirth again exposed, and now suffers from a virulent attack. Here, parturition (which,
as we know, renders women peculiarly susceptible of the contagious fevers) is the predisposing cause, the scarlatinal contagium is the exciting cause, and the inflammatory processes going on in the skin, tonsils, and elsewhere, the proximate cause of most of the symptoms which the patient manifests. But the exciting cause of the scarlet fever is obviously the proximate cause of that disease, and the proximate causes of its several secondary phenomena are just as obviously their exciting causes."

The distinction between the exciting and the proximate causes is thus purely artificial; whereas the differences between the predisposing and exciting causes are generally well marked; but the co-operation of both of these kinds of causes is, however, generally necessary to produce disease.

Predisposing causes of disease differ from a predisposition to disease. The first may be certain influences operating upon the animal body from without, such as heat, cold, vitiated atmosphere, inordinate work, the quality of the food, poisons, &c.; whilst a predisposition to disease is always intrinsic, existing within the animal body, and is very frequently found to arise from some hereditary taint. For example, horses of certain breeds become roarer, or otherwise defective in their wind, from no appreciable cause. Animals thus affected are said to have a hereditary predisposition to these infirmities. In such instances, the predisposition may be truly said to be the predisposing influence which has given rise to the disease of which roaring or other defect in the respiratory function is the symptom; but it cannot be maintained that a violent inflammation of the larynx or of the lungs, when succeeded by roaring, constitutes a predisposition, although they are most certainly the predisposing, and in some instances the exciting causes of the same pathological condition.

Predisposing causes of disease commonly consist of various circumstances which influence the functions or structures of the body in an unfavourable manner, yet short of actual disease; or, in other words, those general, non-specific conditions which by their influence so alter the health of the system, or the condition of parts of it, as to render them specially suitable for the development of certain diseases, provided that an animal so predisposed be subjected to the influence of the excitants of such diseases.

The exciting causes of disease are those circumstances and
agents which, operating on the body, especially when predisposed, may excite disease; amongst them are included those specific causes, or elements of disease, which stamp their individuality on the morbid processes which ensue in the animal body when the germs of such diseases happen to become implanted therein (as in glanders, rabies, rinderpest, scabies, &c.), and are divided into the cognizable and non-cognizable. The first includes all the physical and other agents of whose existence we can take cognizance, independently of their operation in producing disease. The non-cognizable causes, on the other hand, elude our senses, and we infer their existence only from their morbid effects.

The predisposing and exciting causes of disease, when existing within the system, are called intrinsic, endopathic, or internal; but when they arise without the system, they are denominated extrinsic, exopathic, or external causes of disease.

_Predisposing causes of diseases._—The most important and generally recognized predisposing causes of disease are—

(1.) _The influence of age._—This is not so striking in the lower animals as in man, but still it plays an important part. In the dog, for example, the period of dentition renders the animal liable to fits of convulsion, paralysis, disturbances of the digestive process, with vomiting, irregularity of the faecal discharges, weakness, and even inflammation of the eyes, and attendant unthrificniss. Rickets is also a disease which is only seen during the early period of life, and is witnessed in all our domesticated animals, but more particularly in the dog.

Canine distemper may be manifested during any period of life: as a great rule, it is only seen during the first few weeks or months of the animal's existence. Again, the strangles of the horse is generally a disease of adolescence.

It is also well known that the invasion of parasites is much more common during the earlier period of an animal's life; thus we find the _Camerus cerebralis_ developed in the brains of sheep and cattle during the first months of life. The _Strongylus filariae_ of the lamb, and its analogue, the _Strongylus micrurus_ of the calf, seem only capable of inducing disease in these animals in early life. The _Trichonema arvusae_, witnessed by me in Icelandic ponies, and referred to in the latter part of this work, were never found in horses above two years old.
CAUSES OF DISEASE.

The bones are also much more liable to disease during youth than middle age; for example, osteoporosis is rarely witnessed in an animal which has passed its fifth year. I say rarely witnessed, for I have seen two horses affected with this disease, which had passed the age of seven years; but even here I was convinced that the morbid changes had originated during the earlier years of the affected animals' lives.

Again, we find that disease of the facial bones is generally seen in young horses, and is doubtless closely connected with the process of dentition. Nor must we forget to mention that dentition is not always free from attendant ill consequences; in some cases the crowns of the temporary molars are not shed, but become entangled in the newly cut permanent ones, causing difficulty in mastication, indigestion, and unthriftiness, more particularly in horned cattle; whilst in the horse, at about the age of four years, a true dental cough results from irritation induced by the cutting of the sixth molar tooth.

It becomes a matter of speculation whether those causes of lameness which are so commonly met with in young horses are results of predispositions or not. When it is taken into consideration that the bones of the young are more vascular or succulent, contain less earthy matter than those which have arrived at full maturity, and that these young bones are subjected to inordinate work, concussion, and alteration of incidence by erroneous shoeing, we must conclude that there is not always a predisposition to disease, but that disease is induced by subjecting the animal to work which its physiological condition and strength are unable to withstand. At the same time, many animals develop diseases of the bones and joints without the aid of exciting causes, which leads us to conclude that in them there is at this period of life a predisposition to disease.

Both foals, calves, and lambs are very early—indeed often within the first few days of their existence—subject to disease of their articulations, very frequently without any apparent cause. Here we may safely conclude that great vascularity of the extremities of the bones constitutes a predisposing cause of disease.

During the middle period of life, animals as a rule have few special tendencies to disease. Such affections as navicular arthritis, and those conditions of the respiratory tract which give rise to roaring, whistling, &c., are more frequently witnessed during the
middle period; but as the predispositions to these affections are supposed to be hereditary, they will receive further consideration.

The cow is perhaps an exception to that exemption from diseases occurring in middle life, for in this animal we find that when its powers are fully developed, liability to that fatal disease, parturient apoplexy, is much enhanced.

At the approach of old age, and during its continuance, diseases arising from tumours, degeneration of organs and tissues, manifest themselves; the heart, liver, &c. undergo fatty metamorphosis; the circulation becomes feeble; digestion impaired; the blood-vessels, particularly those of the brain, undergo a calcareous change; the joints become stiff; the bones brittle, and the cutaneous surface liable to be infected by various parasites. In the dog, the crystalline lens undergoes a retrograde change, and soft cataracts are commonly seen; whilst deafness and dropsy are not rare amongst dogs of advanced age.

In the ox tribe, again, we find that age influences the seat of disease: for example, in young animals, charbonous disease manifests itself externally, whilst in those of mature age its lesions are generally witnessed in the internal organs.

Sex.—The difference in the organisation of the male and female. In addition to those variations in diseases necessarily arising from the peculiarities of the generative organs of the two sexes, as affections of the testicles, &c. in the one, and of the ovaries or uterus, as well as hysteria, in the other, we find that sex has to a limited extent an influence at least in one disease, which occurs in both sexes; thus roaring is much more frequently met with in horses and geldings than in mares.

Peculiarities of breed and conformation.—In connection with breed and conformation, we often witness predispositions to certain forms of disease; as, for example, canker and chronic grease, common enough in heavy-legged cart-horses, are but rarely seen in the better bred ones. Roaring is very often associated with certain conformation of the neck. Large horses with long necks, particularly if fine or small at the throat, are much more predisposed to roaring than those with shorter necks; smaller horses are more rarely affected, and ponies very seldom indeed become roarsers. Round-chested horses are more liable to become broken-winded.

There are also certain forms of lameness which conformation
and size have much to do with. Ossification of the lateral cartilages is rarely witnessed in the better bred, but is very common in the cart-horse. Navicular disease, so rife amongst better bred horses, is a very rare cause of lameness in the cart-horse; and, not to adduce too many examples, high-bred, nervous animals are more liable to nervous diseases than those of a lower breed.

The effects of colour in predisposing to disease are very curious, as shown in the frequency of melanoid sarcoma, and in the intractability of tumours which do not contain pigment in grey or white horses; and the liability to cutaneous eruptions upon the white parts of the body only has caused one disease to be called “white face and foot disease.”—(Crusta labialis, see Veterinary Surgery.)

Tribe or species.—The influence of species in favouring or resisting certain forms of disease is really remarkable. Thus the horse, whilst liable to glanders, resists diseases to which cattle and sheep are peculiarly liable, such as rinderpest, pleuro-pneumonia, eczema epizootica. Rabies, again, is primarily a purely canine disease. Charbonous disease is transmissible to man and to all the domesticated animals, with the exception of the domestic fowls and birds generally; but here it has been found—and probably this discovery explains why some contagia affect certain animals only—that resistance to charbonous contagion is due, not to conformation, but to temperature; for when the temperature of the fowl has been lowered by removing its feathers and keeping it in water, it has become affected with the disease.

Temperament, which consists in excess of or defect in some function or set of functions, certainly predisposes to particular diseases.

The sanguine temperament, implying an activity of the circulatory and blood-producing organs, tends to diseases of an inflammatory character. This temperament is best exhibited in highly bred horses, whereas in lower bred animals the lymphatic temperament seems to predominate. In this temperament there is a deficiency of arterial tonicity, a want of nervous power, the circulation is languid, the capillary and nervous systems, particularly in the extremities and depending parts of the body, are often congested and edematous, which conditions disappear for a time with exercise. Inflammatory diseases run
an unfavourable course in animals with this temperament, there being a tendency to the effusion of serum, to deliquescence of organs, and to gangrene, and not to the exudation of plastic lymph, as in animals in which tonicity is not defective.

Cattle and sheep are generally considered to possess a lymphatic temperament. This supposition is to my mind hypothetical, for, with the exception of liability to become more rapidly anemic, and infested by parasites when improperly fed, and to suffer from the dropsies associated with the mal-condition so induced, it is found that these animals do not exhibit the same tendency to edematous swellings and other signs of debilitated circulatory powers as the horse, and in the ox particularly lymph is abundantly exuded in some inflammations.

The nervous temperament is manifested by agitation and excitement, and although it is called nervous, it does not follow that an animal possessing it has extra nervous power. Indeed, the contrary is often the case, for an animal of this kind generally becomes exhausted in a very short time. The term seems to imply a want of proportion of some of the functions or properties of the nervous system.

Nervous animals are easily frightened, and a sudden fright may be followed by serious illness, such as violent purgings, loss of appetite, tremblings and excitement, which may continue for several hours or even days, and, what is more serious, sudden death from rupture of the heart. I have seen one sudden death in the horse from this cause—of one that was quite well at the time. In another, not of death, but of serious illness. I have it recorded that an old hunter was seized with purging, loss of appetite, tremblings, snorting with fear, and other symptoms of excitement, which always continued for three days, every time it was shod.

Previous diseases are also predisposing causes of new ones. Thus we find many horses recovering or recovered from an epizootic become the subject of rheumatism in a joint, bursa, or tendon. Catarrhal fever is often succeeded by purpura. Chorea succeeds diatemper in the dog. Lymphangitis predisposes to succeeding attacks of the same affection; and if under this head we classify artificial diseases, as induced by the operation of medicine, purgative, or other evacuant, we can understand how, during the prevalence of the epizootic influence, epizootic
disease is easily excited in an animal which has been physicked a short time previously. Even a surgical operation will, during the prevalence of an epizootic disease, cause its development in an animal previously healthy.

Present disease, and conditions bordering on disease.—Diseases of the heart, causing engorgement of the veins, often lead to congestion of the lungs and liver, dropsy of the cavities and areolar tissue; excessive evacuations, as in diarrhoea and diabetes, predispose to other diseases, as glanders or tubercle; feeble digestive and assimilative powers, to anaemia and dropsies; inflammations, particularly in horned cattle, to caseous tumours, in parts other than those originally inflamed.

Hereditary tendency.—Many diseases, such as curbs, spavin, ringbones, navicular disease, chorea or stringhalt, run in certain breeds of horses; tubercle and scrofula in the best breeds of horned cattle.

Mr. Fleming states that French authors are unanimous in asserting that the disease termed “roaring” in the equine species, and which now generally affects horses in Normandy, was unknown there until the arrival of Danish stallions.

The influence of climate in overcoming hereditary predisposition is well shown in India, where horses the progeny of roarsers are as a rule exempt from this infirmity.

Diathesis, idiosyncrasy, or aptitude.—Diathesis is a term used to describe a particular tendency to certain forms of disease, such as the rheumatic, tubercular, and scrofulous. In animals of this constitution, the particular disease to which they are predisposed, or to which they have a tendency, is caused by different exciting circumstances, and serious diseases are induced by trivial causes, although such animals may present no external signs of idiosyncrasy.

Exopathic predisposing causes.—Whilst the endopathic causes of disease are generally beyond the influence of our preventive power, those existing external to the animal are to a very great extent subject to our control, and, by a careful study of them, we discover that many diseases are preventible. As a rule, however, extrinsic causes are generally excitants of disease, and it would be a needless repetition if I were to describe them here. I shall therefore pass on to—

The exciting causes of disease.—These again present themselves
to us under two heads—namely, the intrinsic or endopathic, and the extrinsic or exopathic. The endopathic exciting causes are—

(1.) **Mechanical**, which include strictures of orifices and tubes, by contraction of their coats, pressure from without, or impacted concretions—as stricture, intus-susception, intestinal or urinary calculi; presence of parasites in the ducts of the liver, in the bronchial tubes and cerebral hemispheres; the pressure of tumours on the brain and other parts of the body; herniae; obstructions in the larynx or oesophagus; nasal polypi, &c.; and

(2.) **Chemical causes**, which include all retained secretions of excretory organs—such as urea and the other products of the metamorphosis of the nitrogenous constituents of the food and body—occurring as a result of disease of the kidneys, or when nitrogenous products are too abundantly present in the blood, as in azoturia. Again, when from some impediment to the respiratory function carbonic acid is retained, the animal may die from delirium and coma. If the liver fails to perform its function, jaundice follows, succeeded by anaemia, dropsy, and death.

Chemical and mechanical causes are also external or exopathic, and include all poisonous substances, mineral and vegetable—as acids, caustic alkalies, opium, strychnia, aconite, lead, &c. &c., and all forms of external violence.

**Disease germs.**—Contagia, morbid poisons, specific disease, poison or virus, are called vital causes of disease, and may be endopathic, as when occurring in the spontaneous development of a contagious or infectious disease (see Origin of Contagious Diseases), and exopathic when such diseases are propagated by infection, contagion, and inoculation.

Exopathic predisposing and exciting causes are those due to the influence of climate, food and water, ventilation and drainage, locality, geological formation, weather and seasons, malaria, work, and the want of it.

Of the influence of climate, the diseases named kumree and burnetee, common in the East, afford well-known examples.

**Food and water.**—The solid and liquid ingesta are fertile sources of disease—1st, by being insufficient or ill-proportioned in quality; 2d, by being deficient or excessive in quantity.

Unsuitability of food, either in consequence of a deficiency, over-abundance, or improper combination of nutritive constituents, is a very frequent cause of disease. This has been
well shown in the experiments of Majendie and others. Dogs, geese, donkeys, and other animals, when fed entirely on sugar, gum, starch, oil, or butter, died with symptoms of starvation, almost as soon as if they had been kept without food. Even bread, when too fine, is insufficient nourishment. A dog fed on pure white bread lived only fifty days, whereas another fed with the coarsest brown bread was well nourished, and seemed capable of living for an indefinite period. Again, according to the researches of a Commission of the French Institute, animals fed on pure fibrin or albumen died of starvation, almost as soon as if not fed at all.

Experiments have proved that in order to support health and strength it is essential that, in addition to water, food contain at least three classes of constituents, namely—(1st.) Nitrogenous, to nourish muscular and other albuminoid tissues; (2d.) Hydrocarbons, which supply materials that undergo combustion in the body, and assist in the maintenance of animal heat and in the assimilation of the nitrogenous compounds; and (3d.) Salines, to supply materials for the building up of the solid structures of the body, maintaining them in health, and assisting in the processes of assimilation and elimination, conveying new materials into the system and removing old ones out of it. If these various constituents are deficient, absent, or present in undue quantities, health cannot be maintained, and common experience has taught that all animals are kept in the best health when fed on a mixed diet. And as types of all proper food we have two examples. (1st.) Milk offers us the best example, as it contains casein—nitrogenous, oil and sugar—hydrocarbons, water and salts. Hence young animals thrive best, and are maintained in health by the food which nature has provided for them. (2d.) Grass may also be adduced as a food containing exclusively all the ingredients required for the support of animal life.

As examples of the bad effects of food good in itself, but ill-proportioned in quality, we may adduce those diseases, namely, fatty degeneration of the liver and anemia, so commonly met with in sheep too exclusively fed on turnips. During good seasons, when the turnips are firm, well-grown, and healthy, they tend to overload the system with saccharine matter, and to induce a degenerative change in the liver, which renders it of a palish yellow colour, friable, and incapable of performing its functions. This condition may be associated with fatness; indeed sheep
so affected begin to die when almost fit for the butcher, and the best plan, when they thus begin to fall off, is to make the remainder of the flock so fed into mutton as soon as possible.

During wet seasons, turnips, although apparently fully grown, may contain but little nourishment, but are loaded with watery particles. Animals then have to consume large quantities to maintain life, and in consequence the digestive powers become weakened; debility, anemia, and death are the results.

Now if the stockowner bear in mind that the fodder with which he is supplying his animals does not contain the essential constituents of sound food, he will avoid his losses by supplementing turnips with cake, corn, and particularly with some long food, as it must be borne in mind that all ruminants thrive best upon food requiring to be remasticated. The horse also, though not a ruminating animal, does not thrive except on food, some of which at least is coarse, and requiring much mastication; and the bad effects of feeding the horse on a diet easily swallowed are seen when it is fed on cooked food or on bran mash es exclusively. I have seen cases of fatal impaction and of rupture of the stomach caused by feeding on bran alone; and my experience points to numbers of instances where severe indigestion, with colicky pains, and fetor of the breath, have been induced when coarse food has been withheld from horses suffering perhaps from a sore throat or other disease.

But whilst hay or straw, which may be called the coarser articles of diet, are necessary, alone they are insufficient to maintain an animal in robust health, as the indigestibility of the quantities necessarily ingested becomes a source of disease, indigestion, broken wind, languor and debility, or lead to such a condition of the system as to predispose it to succumb to the influences of epizootics.

In addition to being insufficient or ill-proportioned, food may be bad in quality, as in rainy seasons, where the vegetation is too watery in its nature, its nutritive constituents washed out as it were; or damaged by mould, or other causes in operation and extending over districts and even countries. What is more common after a bad harvest, hay or corn, than to see scores of horses affected with the disease termed diabetes insipidus, induced by some as yet unknown agent developed in the food by the operation of wet, heating, and fermentation, or all of these operations combined.
Again, it is found that wheat and rye are affected with ergot, and oats with a fungus growth, eminently fatal in its action on the animal body; and that all kinds of forage by becoming rusty acquire unhealthy properties, infected with cryptogamic plants belonging to Uredo or Puccinia species, or mouldy—blue-mould—when attacked by the Mucor mucida.—(See FLEMING'S Sanitary Science and Police on this point.)

Of the bad effects of grass in rainy seasons, when it is loaded with watery particles, numerous instances of tympanitis, diarrhea, and dysentery of a fatal nature, particularly among sheep, are witnessed during wet years.

But if the season be too dry, forage becomes hard, innutritious, and indigestible from want of moisture as one of its constituents; causing constipation, impactions, with their attendant conditions of the body, unthriftness and debility, leading on to anemia, and even death. In young cattle particularly, this condition of the pastures, at first giving rise to indigestion, induces, if long continued, a mal-condition of the osseous system, whereby the bones become fragile or brittle, with stiffness of the joints and liability to spontaneous fractures. In some parts of Scotland a similar condition of the skeleton is brought about by feeding young cattle on turnips grown on land highly dressed with the phosphates, and urinary calculi are not uncommon in animals highly fed on turnips and cake.

Food may be excessive or deficient in quantity. The more common effects of food partaken of in excessive quantities are colics, enteritis, impactions, and ruptures. As a rule, we find that animals partake of food in quantities sufficient to satisfy appetite and maintain health; but there are exceptions to this, and we find some, particularly horses, habitually greedy in their desire for food, eating voraciously, hurriedly, and masticating imperfectly. Others again are voracious from accidental long fasting, and the evil consequences of this kind of feeding are a source of great loss to the horseowner, and of great anxiety to the veterinary surgeon, as most of the fatal cases of disease of the digestive organs arise from this cause. To avoid such loss, a little forethought would go a long way. If a horse be habitually greedy, it should be made to take the edge off its appetite by an allowance of hay before its corn, then be fed sparingly on the latter, and the quantity which is generally
given at once ought to be divided into two or three parts and
given at intervals; if this be not done, colic, rupture, enteritis,
or laminitis may ensue. If a horse seem voracious from long
fasting, a similar course would often avert an attack of perhaps
a fatal disease; and at all times, if it be deemed expedient,
owing to a damaged condition of the grain, to give cooked food
—an unnatural kind of food for horses, cattle, and sheep—it
ought to be given in small quantities, and often.—(See Diseases
of the Digestive Organs, also effects of Potatoes.)

Food defective in quantity or nourishment causes debility,
wasting, oedematous legs, susceptibility to the attacks of parasites,
anæmia, dropœy, and even death.

Clusat found that in animals gradually starved to death the
temperature of the body progressively declined, and unless
maintained artificially, the animals seemed to die of cold. All
the textures, even the bones, sustained great loss of weight, but
those of the nervous system less than any others.

Sudden change of food, even if it be of good quality, is
often a cause of disease. For example, what is more common
than a sudden outbreak of disease amongst cattle, particularly
young ones, hardly kept in the winter, when first turned into
rich pastures. The same applies to sheep, and I have often
witnessed a fatal form of enteric disease amongst sheep—in one
instance extending to cattle and horses—when depastured
during early summer upon land lately drained and limed.
So great was the fatality, that the farm seemed unfit for
grazing purposes, for, after liming and draining had been
completed, the more benefit the land seemed to derive from
the cultivation and the richer the pasture, the greater the
mortality.

The influence of water.—Much prejudice exists, particularly
among horsemen, as to the use of water. In consequence of
this we find that hunters and racehorses are severely punished
before they are called upon to hunt or race, by having but a
very limited and insufficient allowance of water prior to the
performance of their task. What harm a sufficient supply of
water, partaken of several hours before the hunt or race, can
effect, is beyond my comprehension; indeed I have found that
a hunter properly fed and watered on a hunting morning has
been enabled, provided always that it is otherwise in condition,
to do its work with greater ease, and to last longer than animals deprived of so necessary an element as water.

Water containing organic impurities, or too hard from the over-abundance of earthy salts—that is to say, water containing more than twelve degrees of hardness—is apt to induce disease.

Burton, in *First Footsteps in Africa*, says, at Zeyla, a large Somal town on the East Coast of Africa, all the pits within the walls supply brackish or bitter water, fit only for external use, and that is the reason why vegetables are unknown, and why a horse, mule, or even a dog, is not to be found in the place.

Organic impurities, either suspended or in solution, and more particularly during the hotter months of summer, are apt to induce diarrhoea, anthrax, and putrid diseases, which may prove fatal. Animals certainly seem to become habituated to impure water, and sometimes prefer it to that which is clean and wholesome, but even these are not exempt from its evil consequences; and indeed the very depravity which leads them to prefer what is so unnatural may be looked upon as of itself a diseased condition.

It is stated that water taken at a comparatively high temperature for some time induces debilitating effects, disorders the digestive apparatus, and predisposes to catarrhs of the alimentary and respiratory passages.—(FLEMING.)

But, as a rule, however, pure water may with benefit and advantage be allowed in such quantities as the animal seems to require, taking its condition into consideration at the time. If it be heated or exhausted by work, water must be supplied in moderate and repeated quantities, and not too cold, until its thirst is assuaged, or enteritis, diseases of the skin, or inflammation of the feet, may result. With this exception, I repeat that water ought at all times to be freely but judiciously allowed.

Water in the form of dew or hoar frost is believed to be a cause of disease. It is very possible, if a very hungry animal were to eat dew-covered grasses ravenously and quickly, that digestive disturbances might arise; but I fail to see how food, masticated and retained in the mouth until its temperature is elevated almost as high as that of the body, can be inducive of disease. Mr. Fleming tells us *(Sanitary Science and Police)*
that honey-dew has been supposed to cause aphthous and other affections. "Intelligent agriculturists in Saxony have remarked this dew as a cause of epizootics, and the shepherds take the precaution of leaving their crook on the grass in driving home their flocks, and examining it in the morning before driving them out again. If they observe the dew which has gathered on the crook to be only water, the flocks may then be allowed to pasture; but if it resembles oil or honey, then they must remain until the dew has evaporated."

Geological formation and locality.—Mr. Robertson, Kelso, in his little work Hints to Stockowners, says—"The substrata on which soils rest, and to which in part they owe their formation, is always an important element in determining their character, and one which remains undisturbed in its permanence, notwithstanding cultivation, and the improvements of modern scientific agriculture. From an acquaintance with the nature of this formation, we can in many cases predict what will be the character of the stock bred and reared on such lands, as also the diseases to which they are more particularly liable, or from which they are exempt. For example, it is a fact well known to the majority of our sheep-breeders, that on certain soils, chiefly those resting on the igneous rocks, sheep are liable to suffer from a form of abdominal consumption, known as "praying," and that no system of treatment is so efficacious as their removal to soils resting on the sandstone formation. There are also diseases of particular structures of the animal body, as the bones and nervous system—"szootic"—that is, confined to circumscribed districts of country, which seem to owe their origin to the redundancy or absence in the soil, and materials grown thereon, of certain organic or inorganic materials. These diseases are always difficult of prevention, when only methods of cultivation, or systems of folding the animals on these lands, are adopted. They would require to have access to those situations known to be dangerous only at particular periods, and to have what food is given them from such soils supplemented by others of a very different nature."

In several parts of Scotland, it is well known that stock suffer to an enormous extent in certain pastures during spring, or until the appearance of the white clover. It is difficult to account for this, unless by the supposition that, owing to the geological
formation of such districts, the grasses, no matter how abundant
they might be in quantity, are defective in some constituents, and
calculated rather to induce disease than support life, until such
grasses have attained a certain age, coincident with the period of
the blossoming of the white clover.

In soils deficient in certain mineral constituents, the plants
grown thereon will also be deficient in those, if not artificially
supplied; as, for example, as stated by Mr. Fleming, there is no
phosphate of lime in the soil of the alluvial tracts in the banks
of the Rhine. What is necessary for the growths of plants is
derived from the atmosphere, which supplies no less than 400
grammes to each hectare, according to Burrell, and which is devo-
sited by the rain. In dry years, however, this supply fails, and
the plants are then deficient in this most essential ingredient.
The consequence is, that the creatures which consume these plants
suffer more or less, and this is now recognised as one of the causes
of that special affection of the bones of animals in those regions
which has received the name of Osteoclasy.

It is well known in Scotland that certain nervous diseases,
more particularly that known as "louping-ill" in lambs, are
only witnessed in certain localities,—very often the breadth
of a river being sufficient to separate the unhealthy from the
healthy ground. Many sheep-farmers and shepherds have long
believed, what is now demonstrated to be the case, that "louping-
ill" is only seen upon land infested with ticks, and that ticks
are the cause of the disease; while it is possible to have land
infested with ticks, and yet have the sheep free from louping-
ill, as all ticks do not seem to contain disease germs, and it is
clearly proved that louping-ill is not seen where ticks are
absent.—(See "Louping-Ill").

The influence of marshes and undrained lands in predisposing
to and exciting disease is well known, and need be merely
referred to here. Such diseases as rheumatism, dysentery, and
typhoid diseases in animals, and intermittent fevers in man,
are traced to the influences—malarial—of such lands. It is now
demonstrated that anthrax diseases are due to a specific germ,
the Bacillus anthracis, and that they cannot be developed except
by the introduction of the germs into the animal body. The
subject will be discussed hereafter: at the present, I have only
to state that moist lands have a great influence on the develop-
ment of anthrax, and that since this country has been to a
great extent drained, at least one form of anthrax, namely, gloss-anthrax or blain, has disappeared. Again, rot in sheep, as well as other parasitic diseases, prevail to a much greater extent on damp than on dry soils, and the influence of a wet season, even on dry and well-drained soils, induces the development of many diseases, amongst which the grouse disease may be cited.

Imperfect ventilation, to which may be added defective drainage, is a fertile cause of disease; indeed it may be stated that defective ventilation is a source of greater loss to owners of horses than all other causes of disease combined, particularly in large towns. A deficiency of oxygen, excess of carbonic acid, and a scanty supply of fresh air, stint the vital processes, and the gradual accumulation of the ammoniacal products of the decomposition of excrementitious matters by which animals are surrounded, are almost certain excitants to diseases, particularly those of the respiratory organs; and when disease is once excited by such causes, a recovery becomes almost an impossibility until the sufferer is removed from their influence. It will be pointed out hereafter that in the treatment of lung inflammation, pure air is an absolute necessity; and if we bear in mind that impure air is often a cause of this inflammation, can we wonder at the fatality of diseases when animals suffering from such a disease are kept under the very influences which have induced its development? Let the owners of thorough-bred stock, who have lately suffered serious losses, reflect that, no matter how skilful the treatment of such animals might be, it is futile so long as the operation of causes is not taken into account.

In large horse establishments scarcely a fresh animal arrives which is not shortly laid prostrate, not so much by change of locality and food, as by the direct influence of a contaminated atmosphere. After a time, however, even the horse may become habituated to some extent, and present all the signs of health; but if an epizootic influence at any time prevail, an animal so circumstanced is always the first and the most seriously to suffer.

With regard to the drainage of stables, I am of opinion that within the buildings they should be on the surface, and that the grating leading to a necessary underground drain should be some feet upon the outside of the stable walls. Where drainage is
bad, disease is apt to assume a pyæmic character, and an ordinary inflammation may lead to the formation of multiple abscesses, purulent infiltrations, or even gangrene.

Work—over-exertion—by its debilitating effects, tends to induce disease: for example, we have congestion and apoplexy of the lungs, as well as laminitis, myositis, and spasm of the diaphragm, from severe exertion, especially when a horse is not in condition; and from the more continued over-work, as seen in cart-horses, stiffness of the joints and back, unthriftiness, a tendency to and actual development of diabetes, and its sequelæ, farcy and glanders.

Exercise is beneficial to all animals, but when in degree or continuance it exceeds what the strength can bear or rest can recruit, the animal functions are exhausted and lose their balance, muscular tone is impaired, nervous excitability takes the place of strength, the circulation fails, congestions ensue, the blood is not properly purified, and the various organs are on the brink of disease. Hence it is that animals which do not actually become diseased from over-exertion are more prone to succumb to the influence of any epizootic that might prevail at the time.

Want of exercise is a frequent cause of disease; the muscular system, and with it the circulation of the blood, is the first to suffer, the movements become sluggish, sweats break out upon the least exertion, there is want of condition, in horse phrase, swelled legs, grease; the respiration being but little exercised, the task of decarbonizing the blood falls upon the liver, hence the accumulation of fat and the occurrence of derangements of that organ.

Heat and cold are very prevalent causes, and act as follows:—Heat relaxes the whole system; under its influence the muscles, and with them the heart and arteries, lose power and tone, perspiration becomes profuse, the internal organs especially are too much stimulated by blood which has lost more than usual of its water, and less of its hydrocarbon. You will often find that upon the sudden accession of hot weather horses suffer greatly from congestive diseases. In May and June 1867 this was the case in Bradford. The weather had been cold, but very suddenly it became hot, and immediately numerous cases of congestive hepatitis occurred; in other seasons we had to contend
with congestive pneumonia. Cold again acts as a sedative and debilitant if long continued or severe; it weakens the circulation, especially that of the surface of the body, causes internal congestions, and directly lowers all the vital energies; and the most fatal cases of pleurisy and pneumonia are observed to prevail during and towards the close of severe winters. A temporary application of cold to the healthy animal is followed by a favourable and invigorating reaction, but when long continued its effects are most injurious.
CHAPTER III.

PATHOLOGY—continued.

THE MORBID PHENOMENA—SYMPTOMS AND SIGNS OF DISEASE—SEMIOLGY.

"For my own part" (says Watson), "if I were called to define a symptom, I should say, 'Every thing or circumstance happening in the body of a sick person, and capable of being perceived by himself or others, which can be made to assist our judgment concerning the seat or nature of his disease, its probable course and termination, or its proper treatment.' Every such thing or circumstance is a symptom."

Symptoms are signs of disease, but it is only by mental effort and experience that the practitioner is able to convert symptoms into signs. The idea associated with symptom is much more vague than that which is connected with sign. Some writers have endeavoured to restrict the word symptom to the phenomena depending on vital properties, whilst those phenomena of disease which are more directly physical are by them called signs. Again, some restrict the term symptom to the phenomena manifested by present disease only; but this is contrary to the custom by which we speak of precursory and consecutive symptoms. Symptoms of disease are obvious to all persons alike: for example, the manifestation of pain, the symptoms in an animal suffering from enteritis, are plainly seen by all the surrounding attendants, but it is only the skilled and experienced veterinarian who can detect the expression, the condition of the pulse, &c., the signs by which this malady is diagnosed or distinguished from a mere colic. "Symptoms may be considered as resembling so many words. When taken separately, or when put together at random, the words have no force or signifi-
cuation. Arrange them in due order, reduce them into a sentence, and they convey a meaning. The sentence is a sign or expression of something which is thus revealed. Symptoms become signs when their import can be interpreted."—(Sir Thos. Watson.)

According to the arrangement of Reynolds, symptoms are to be considered as parts of a disease, for he says—"So long as disease was regarded as some material put into, added to, or engrafted upon the body, the words symptom or sign described the means by which we might recognise the presence of such a material; but when we define disease as being the sum of changes in function and structure presented by the living being, the words symptom and sign describe only those parts of the disease which are appreciable to the observer's senses. We call a disease by a particular name, which may express its primary or most important fact, but we cannot separate this one fact from others, as exhibited by the symptoms, but must regard them as integral parts of the malady. Thus the different phenomena of pneumonia, the cough, lung-sounds, respirations, &c., are as much parts of the disease as are the structural changes in the lung. We cannot imagine the existence of symptoms without disease, and vice versa." I must, however, differ from the above-named writer, as I am strongly convinced that when symptoms are thus arranged they are apt to be therapeutically looked upon with too much significance, and thus induce the practitioner to pursue a course of treatment more calculated to modify them than to remove their causes.

Symptoms are local or general, according to whether they are confined to the diseased part, or affect, more or less, the whole system; idiopathic, when directly proceeding from the disease; sympathetic or secondary, when arising from those produced by the primary disease, or from secondary disorder; premonitory or precursory, when they precede the full development of disease, generally resulting from the first operation of its cause, such as signs precursory to an inflammation; commemoratives, when developed in the previous history of the disease. Again, symptoms and signs are further divided into diagnostic, prognostic, and therapeutic, when they are specially applicable to the distinction, the determination of the event, and the suggestion of the treatment of the disease; into objective, when they present themselves to the scrutiny of the practitioner; and these
are again divided into the active or dynamical, when they are only discoverable by motion or manipulation, and the passive or statical, when they are obvious without such action; positive, when they consist of phenomena actually present, and negative, when they consist in the absence of phenomena. Diagnostic symptoms are those symptoms which point out the distinction of one disease from another, and the art of diagnosis is that by which the practitioner is enabled to arrange symptoms into signs of disease. A symptom or a set of symptoms which are peculiar to any particular disease, are said to furnish pathognomonic signs of such disease, and are called pathognomonic or pathognostic. A simple symptom is rarely pathognomonic, but two or three conjointly often are so. For example, a discharge is seen to issue from a horse's nose. This is a symptom. It may, however, be due to a catarrhal inflammation, to disease of the teeth, or of the bones of the face; to an affection of the lungs, to a collection of pus in the guttural pouches or facial sinuses, or to glanders. The discharge is so far a sign, that it indicates the formation of pus. If we discover, on examination, that the discharge is associated with ulceration of the Schneiderian membrane, with enlargement of the submaxillary lymphatic glands, and more especially if the discharge itself is of a glutinous consistence and starchy appearance, we conclude that it is due to glanders. Taken collectively, these symptoms constitute a diagnostic sign of glanders, and are said to form the pathognomonic symptoms.

The interpretation of symptoms requires the closest observation, and in many instances repeated examinations of the patient; for the veterinarian is never assisted by what are termed in human medical practice the subjective signs of disease, namely, the sensations felt and described by the patient himself. In veterinary practice all signs and symptoms are objective, and each sign or group of signs has to be duly considered, compared one with another, and each with all; so that a close observation is essentially necessary before a due and proper conclusion can be arrived at and an opinion pronounced. It is by comparing at intervals the various modifications and alterations which occur in the signs and symptoms of disease, that we are enabled to prognosticate the nature of its termination, or, in other words, to make our prognosis.
CHAPTER IV.
PATHOLOGY—continued.
GENERAL SYMPTOMS OF DISEASE.

THE VISIBLE MUCOUS MEMBRANES.

The general appearance of the visible mucous membranes is of great assistance to the veterinarian in the diagnosis of disease. The natural colour of the Schneiderian membrane and conjunctiva is a palish red, or carnation; any appreciable deviation from this is indicative of some disorder. Increased vascularity and heightened colour—floridity—are indicative generally of disturbance and over-excitement of the circulatory system. It does not follow of necessity that disease is present, as the same condition of the membranes is brought about by severe exercise; in fact, any cause of excitement may produce increased redness and vascularity of the visible mucous membranes. This condition is not usually apparent in the tongue and mouth, for the epithelium, more particularly on the tongue, is sufficiently thick to obscure any increased vascularity.

The appearance of the mouth, however, is occasionally of great importance, redness of it being indicative of an irritable and congested condition of the digestive organs generally; vesication, of sporadic or epizootic eczema; a peculiar yellowish or salmon colour, with desquamation of its epithelium, more particularly in the neighbourhood of the incisor teeth and within the lips, of rinderpest; whilst sudden pallor of the mouth and tongue, with coldness, is symptomatic of approaching death from hemorrhage. The appearance of petechial spots on the visible mucous membrane denotes a depraved condition of the blood, as in purpura. Yellowness of these membranes indicates disease of the liver; lividity, a carbonized or non-oxygenated condition of the
blood, as in bronchitis and pulmonary congestion; a state-coloured appearance, a condition of the blood due to the poison of glanders, or a state of the system predisposing to that disease; rusty colour, some forms of epizootic diseases; pink, or pink-eye, epizootic cellulitis; pallidity, anemia and general debility, or, if occurring suddenly, hemorrhage. Meré fulness of the capillaries of these membranes, with increased redness, is not always dependent on an increased circulation, for in many diseases, where the powers of the circulatory organs are much diminished, the colour and vascularity may be greatly augmented. In several cases, where death was approaching from a degenerate condition of the structure of the heart, I have noticed that the visible membranes became very greatly congested, and their colour increased; but the shading of the colour has been different to that seen in inflammatory diseases; the circulation in the vessels has been sluggish; the power of the heart—vis et tergo—has been insufficient to propel the blood through the minute capillaries; hence the congestion. The purplish line mentioned by some writers as being indicative, when not dependent upon an altered condition of the blood, of debility, has not been present in these cases; indeed the difference, except in the shading of the colour, from the appearance in many inflammatory diseases has been very slight; whilst the state of the heart itself has been recognised by violent palpitations, great irregularity of its action, and almost imperceptibility of the pulse at the jaw and arm. A foul appearance of the mouth and tongue, so valuable an aid to diagnosis in human medical practice, is rarely observable in the horse and ox, but is commonly seen in the dog. However, in some forms of dyspepsia, a slightly foul and soapy condition of the buccal membrane is seen even in the horse and ox, with an acid condition of the salivary secretions, which smell sour and even fetid. Dryness of the mouth is often indicative of inflammatory diseases, more particularly those affecting the organs of digestion. A moist state of the mouth, from excessive secretion of saliva, is symptomatic of disease of the teeth, of catarrhal disease, tetanus, or of the presence of a foreign body, such as a pin or thorn, in some of the oral structures.
SYMPTOMS FURNISHED BY THE CONDITION OF THE SURFACE OF
THE BODY AND EXTREMITIES.

In a state of health, if the animal is dry and not exposed to
extremes of temperature, the surface of the body and the ex-
tremities present a warm genial sensation to the touch of the
observer, but the variations of temperature in disease are great
and important. In severe inflammatory diseases, the legs, ears,
and general surface of the body may be cold; the legs and ears
presenting a sensation, when handled, of being what is termed
"deathly cold." This symptom, if continuous, indicates grave
diseases or important lesions; and if, in addition to the coldness
of the legs and ears, there be perspiration over the body, or
what is termed a cold sweat, the life of the animal is in great
jeopardy.

In milder diseases, and those which run through their course
slowly, such as many epizootics, peculiar alternations in the tem-
perature of the surface and extremities are generally witnessed;
thus one leg may be cold while the other three are warm, or
three legs may be cold and one warm, one ear cold and the oth-
er warm, &c. &c. This eccentricity is often increased by
the warm and the cold condition becoming more or less
suddenly changed in situation; the leg which was warm in the
morning may be found cold in the evening, the cold leg or legs
being warm.

The signs furnished by these alternations are indicative of
a depressed and erratic nervous force, and of a tendency to
metastatic congestions.

A dry, scurfy appearance of the skin is often a symptom of
indigestion, and of the presence of oxalic acid salts in the blood;
and what is called "hide-bound," a condition where the skin
seems to have lost its pliability and softness, is a symptom of a
general state of mal-nutrition, arising from indigestion, improper
food, worms in the intestinal canal, or a want of proper exercise,
&c. A staring coat often accompanies the above described con-
ditions,—very often a staring coat is the only symptom of ill
health. Whenever an animal is seen disposed to shiver, with
staring of the coat, upon exposure to moderate cold, or where
this tendency exists in an animal whilst not so exposed, in all
probability such an one is bordering on disease. A persistently staring coat, without any other symptom of disease, often indicates the incubative stage of glands or farcy, and recurrent rigors are generally the fore-runners of strangles or other suppurative diseases. The premonitory stage of lymphangitis is marked by a fit of rigor or shivering, and in one case which came under my notice, acute glands was ushered in by a continuous shivering fit of three days' duration.

THE PULSE.

The pulse is the beating of the arteries, and is usually felt at the jaw—the submaxillary artery, or on the inner side of the arm—the brachial artery. In the cow, whilst recumbent, the pulse may be very distinctly felt on the posterior part of the fore fetlock, and in the dog it is best felt at the femoral, on the inner surface of the thigh.

The pulsations felt by the finger are principally due to the fact that the artery expands during the contraction of the heart, and returns to its previous condition during the relaxation of that organ.

The arterial movements, as indicated by the sphygmograph, constituting the pulse, are described as follows by Dr. Burdon Sanderson:

"1. At the moment that the heart begins to contract, a vibratory movement of the blood contained in the aorta is produced, in which the molecules of liquid are projected forwards in the axis of the vessel. A similar vibratory movement occurs the moment the ventricles cease to contract. These two movements differ only in this respect, that in the former the primary shock is directed towards the periphery, in the latter towards the heart.

"2. Each of these movements is propagated in the direction of the stream at a rate of about ninety feet per minute,—the one expressing itself at the radial artery by a sudden expansion of the arterial tube, the other by a sudden collapse.

"3. The exact moment at which each movement occurs is indicated by the sphygmograph,—the former by a sudden vertical ascent of the lever, the latter by a descent. In either case the primary movement is followed by a succession of smaller move-
ments in alternately opposite directions. By measuring the
time which intervenes between the first and second vibrations,
the exact duration of the systole of the heart may be ascertained,
for the one occurs at the instant that the ventricle hardens in
contraction, the other at the instant that the aortic valve be-
comes tense in closing.

"4. Both movements manifest themselves with much greater
distinctness in some cases than in others. In this difference
it seems probable that the respective valves have much to do,
and that the systolic vibration is produced by the sudden
tightening of the mitral valve, just as the diastolic vibration is
due to the sudden tightening of the aortic valve. The precise
physical conditions on which the degree of vibration depends,
have not as yet been ascertained, but observation points to the
conclusion that the intensity of the systolic vibration is greatest
when the arterial pressure is lowest at the close of the diastolic
period.

"5. From the moment that the ventricles begin to contract,
the fulness of the arterial system, and consequently the arterial
pressure, rapidly increases. As, however, the arteries at first
yield readily to the tide of blood, the tension does not attain
its maximum until some time after the hardening of the
ventricles in contraction. The duration of the interval between
the one event and the other—that is, between the closure of the
mitral valve and the moment of highest pressure in the radial
artery—varies. It is longest when the arterial system is full;
shortest when it is comparatively empty. Hence the measure-
ment of this interval comes to be of considerable importance.

"6. From the moment that the artery attains its greatest dis-
tension, it begins to collapse; the form of that part of the
sphygmographic tracing which corresponds to the period of
relaxation is, as has been recently pointed out by Dr. Rivers,
parabolic. In the normal pulse the parabolic form is not easily
distinguished, the line of descent being nearly rectilinear; but
in all those pulses in which the collapse is rapid, it is very
obvious, and most of all in what has been called the mono-
crotous—single—form, which corresponds to the thready pulse
of authors.

"7. In certain conditions of the circulation, the radial artery,
immediately after the distension produced by the contraction of
the left ventricle, suddenly collapses, and then as suddenly expands again, the second expansion being sometimes nearly equal in intensity to the first. This constitutes diastasis.\textsuperscript{1}—(Dr. Burdon Sanderson's \textit{Handbook of the Sphygmograph}, to which the reader is referred for further information.)

I have already stated that the pulse is the beating of the arteries. In each pulsation as felt by the hand the arteries are slightly expanded, distended, and elongated by the wave of blood; sometimes they are laterally displaced, and then return to their original position, after which there is a short period of rest—the interval.

It seems probable that when the heart contracts of itself, it does so gradually and peristaltically, its constituent fibres being brought successively into action; and that, in so far as the movement is deprived of its automatic character by the influence of stimuli acting through the spinal cord, it becomes sudden and instantaneous.—(See on this point Dr. Burdon Sanderson, or Dr. Bell Pettigrew's Paper on the Physiology of the Circulation, in \textit{Lancet}, 1872.) The influences concerned in the production of the pulse are those of the heart, the arteries, and the blood. The heart gives the impulse by which the expanding wave of blood is carried onward, after which the artery contracts in virtue of the elasticity of the yellow fibrous tissue which enters into the composition of its middle coat, or by its additional muscular force.

In health there is a nearly uniform relation between the frequency of the pulse and of the respiratory movements; the proportions being, as nearly as possible, one respiratory movement to three or four pulsations. Thus the pulse of the healthy horse beats about forty times per minute; the respirations are from twelve to fifteen in the same time. In the cow the same relationship does not exist, even in health, between the pulse and respiratory movements; for during ruminating it may be observed that the pulse is seventy to eighty a minute, and the respirations not more than ten. Indeed the pulse of the cow in a state of confinement, in so far as regards the number of its beats, cannot be depended upon in the diagnosis of disease; the states of pregnancy and obesity, the effects of artificial food, and of the activity of the lactiferous glands, as well as the excitement caused by the act of ruminating, generally produce such

\textsuperscript{1} Double pulse.
an impression upon the nervous system as to cause the action of the heart to be much increased, such increase being entirely consistent with a state of perfect health in an animal so circumstanced.

The relation between the pulse and respiratory movements, with the exception above mentioned, is generally maintained where the pulse and respirations are naturally accelerated, as after exercise; but in disease it generally ceases to exist. In many diseases accompanied by increased frequency of the pulse, the acceleration of the respiratory movements bears no comparison to the increased number of the pulsations, and in many other cases the respiration may be very rapid without a proportionate increase in the number of the pulsations; in some instances the pulse may actually fall below its normal standard, whilst the respirations are increased.

The natural pulse of the horse beats about forty times a minute, that of the cow about from forty to fifty, with the exceptions already mentioned, and the pulse of the dog ranges from eighty to one hundred, depending upon the size and breed of the animal, and the pulse of the sheep from seventy to eighty.

The frequency of the pulsations, and the regularity and irregularity of their succession, depends upon the heart, and the pulse at the jaw and arm, when it can be felt, always corresponds to the contraction (systole) of the ventricles, allowance being made for the very slight interval that must elapse before the wave of blood reaches these parts. To the heart's action must also be referred most of the healthy conditions as well as many of the peculiarities in disease; but the vital condition of the arterial system is not without its influence on the character of the pulse.

The arteries are gifted with a certain amount of vital contractility or tone, given to them by their muscular coat, upon which their healthy firmness depends; without this tone they become relaxed and flaccid, yielding readily to the force of the wave of blood, and but slowly recovering their calibre when the expanding wave has passed onwards. It is evident that, in this condition of the vessels, a portion of the impulse of the heart, which is expended in dilating the arteries, is not restored to the blood by the contraction of their coats; the impulse being thus gradually diminished as the arterial wave proceeds on its course,
the pulse becomes weak, and is not in such instances to be considered a proper indication of the cardiac contraction. The contraction may be strong while the pulse is comparatively feeble. As a rule, however, except in valvular incompetency or muscular degeneration of the heart, there is a general correspondence between the cardiac and arterial pulsations, which renders the one a tolerably correct measure of the other. The quantity of blood also has undoubtedly some influence on the character of the pulse. When it is deficient, the pulse is likely to be smaller than natural. This is not an absolute rule, for in animals which may be considered to be in a plethoric condition the pulse is sometimes comparatively small. A modification of the quality of the blood affects the pulse, and this is most especially exemplified in cases of blood disease, such as haemo-albumenuria and purpura haemorrhagica, where it is frequently found that the pulse is "double," "fluttering," or "trembling."

The varieties of the pulse which are described by authors as being recognizable by the touch are—

(1.) As regards the number of pulsations within a given time, the pulse is said to be frequent or infrequent,—pulseus frequens, pulseus rarus.

(2.) As regards the time which seems to be occupied by each beat, the pulse is said to be quick or slow,—pulseus celer, pulseus tardus.

(3.) As regards the dilatability of the artery in length and breadth, the pulse is said to be large or small,—pulseus magnus, pulseus parvus.

(4.) As regards the compressibility of the artery, the pulse is said to be hard or soft,—pulseus durus, pulseus molis.¹

THE SYMPTOMS AFFORDED BY THE PULSE.

The frequent pulse—pulseus frequens.—Frequency of the pulse, or its number in a given time, varies slightly within the limits of health in animals of the same breed and similar conformation, and more so in animals of different breeds and temperaments. If the standard in the horse be set at forty beats per minute, it is not at all inconsistent with health to find it differ ten beats in two animals differing but slightly in breed and configuration. Thus, one may have a pulse of thirty-five and

¹ Dr. Buxton Sanderson: Handbook of the Sphygmograph.
the other a pulse of forty-five per minute, and both may be in a state of most perfect health; but a difference beyond this indicates some degree of excitement, or some amount of disease.

A frequent pulse—say a pulse above fifty-five per minute—if the horse is not in an excited state, from exercise or other accountable or natural cause, indicates a fevered condition, but not necessarily an increased vigour of the system; on the contrary, a very frequent pulse is generally associated with extreme prostration and debility. A certain quantity of blood is requisite to the existence of the several parts of the body; and when the heart is too feeble to act forcibly, it is compelled to excessive frequency of contraction to compensate for such want of strength. Excessive evacuations either of blood or of any of the secretions are generally attended with frequency of the pulse.

The old belief that "bleeding lowered the action of the heart and arteries," is disproved by the fact that all evacuations increase the number of the pulsations. I have repeatedly observed the effects of bleeding upon a healthy animal, and found that when from three to five quarts of blood have been withdrawn, the pulse has increased in frequency ten to twenty beats per minute; when the bleeding has been pushed beyond this, say to the extent of from seven to ten quarts, the pulsations have risen to extreme frequency—to 100, 120, or more per minute. As the pulse increases in frequency it becomes diminished in volume, supporting the conclusion that a pulse is small in proportion to its frequency.

The quick pulse—pulsus celer.—This term is made use of to denote that condition of the circulation in which the heart accomplishes its contraction almost instantaneously. The terms quick and slow have been objected to by Sir Thos Watson, as over-refinements, "simply because it was not certain what was meant by the terms by those writers who used them," and that it was very doubtful whether the quality of quickness or celerity of each pulsation could be truly appreciated by the finger. But the terms are now revived, for the qualities which they express are made manifest by the use of the sphygmograph, an instrument by which the movements of the artery are transferred to paper, in such a manner as to render it possible to measure their extent and relative duration.—(See Dr. Burdon Sanderson's Handbook of the Sphygmograph.)
Quickness of the pulse differs from frequency. Quickness refers to the time occupied by each beat of the pulse, whilst frequency has reference to the succession of the pulsations. A frequent pulse is that in which the number of beats is greater than usual in a given time; a quick pulse is that in which each beat occupies less than the usual time, though the whole number may not be much increased. Quickness of the pulse is not so difficult to appreciate by the touch in the larger domestic animals as it seems to be in man, and for the reason that the approach to frequency and quickness is normally much greater in man than in the horse and ox. The contrast, therefore, between abnormal quickness and the natural condition is more manifest in the latter than in the former.

Quickness of the pulse is due to the mode in which the ventricles contract, and always indicates irritation and little strength; the heart makes a quick, short contraction, which differs much from the somewhat prolonged, and more or less forcible, contraction of real energy and excitement. The jerking pulse is a modification of the quick pulse, and is characterised by a quick, forcible beat, followed by a sudden abrupt cessation. This pulse is found in cases where the nervous irritability is much increased, or it may be due to some deficiency in the aortic valves.

The slow pulse—pulsus tardus—or, as it is termed by Dr. Sanderson, the long pulse, is the reverse of the quick pulse, and indicates a prolonged or slow contraction of the cardiac ventricles. In inflammatory fever the pulse was formerly described as frequens magnus et color, and was said to differ from that of plethora, which was described as magnus et tardus,—distinctions which are not now held to be competent.

An infrequent pulse—pulsus rarus.—This kind of pulse is often associated with slowness, and indicates disease of the brain (compression), a disordered condition of the digestive apparatus, and is often indicative of that condition of the system manifested by excessive urination—polyuria. In degenerative disease of the heart the pulse is often more infrequent than the cardiac contractions, because the impulse of the heart is too feeble to be transmitted to the arteries.

The mutual relation of the pulsations may refer to their succession, their comparative duration, and their strength. In
all these respects the pulse is often irregular, and the source of the irregularity is to be found in a deranged or debilitated action of the heart. An *intermitting pulse* is that in which a pulsation is occasionally omitted. This omission may be regular, occurring at the end of a certain number of beats, or it may be irregularly intermittent, and along with intermission of its beats there may be irregularity in its tone, volume, &c. For example, several beats may occur in rapid succession; these may be followed by others at long intervals, or some beats may be strong, others weak, some quick, others prolonged; and often several run on successively of one character, to be followed by more or less of another character. Occasionally all these irregularities, or most of them, may occur in the same subject. They are indicative of important functional or nervous disorder, or of organic disease of the heart. An intermitting pulse may often be observed in horses presenting all the appearances of perfect health; indeed, an intermitting pulse is very commonly met with in the cart-horses of this city; and, reasoning from the frequency of indigestion, and the nature of their food, one is forced to the conclusion that this irregularity of the heart’s action is due to some disorder of the digestive apparatus. When these animals are attacked by any disease, the irregularity of the pulse frequently disappears for a time, or until the animal is restored to its former condition of apparent health.

The *volume of the pulse* may be greater than usual, in which case it is said to be *large—pulsus magnus*, or it may be less than usual, when it said to be *small—pulsus parvus*. Largeness or fulness of the pulse may depend upon general plethora, or a prolonged and forcible contraction of the ventricles; to a certain extent on relaxation of the arterial coats, and on obstruction of the capillaries, without diminished power of the heart. It may be associated with *strength* or with *feebleness* of the pulsations. It is important not to confound a full feeble pulse with a full strong one. The feeble pulse is known by the weakness of the impulse, and by the artery yielding to the pressure of the finger. In pulmonary congestion of a severe character the artery is full, and the pulsations feeble. This has been called the “*oppressed pulse of pneumonia*” by veterinarians, and depends upon excessive congestion of the pulmonary vessels. A pulse of this character is improved in tone by a moderate abstraction of blood.
The feeble pulse, if associated with softness, the artery yielding readily to the finger, indicates general or cardiac debility. It is sometimes so weak as to give one the idea that the artery is filled with air, hence it has been called the gaseous pulse, and is not unfrequent in an anaemic condition of the body.

The small pulse—pulsus parvus—may result from anaemia; from congestion of some important organ, as the lungs; from feeble contraction of the heart; or from great tonicity of the arterial coats.

The hard pulse—pulsus durus—hardness of the pulse, is that property by which the artery resists compression, and results from contraction of the muscular coat of the arterial walls. Hardness of the pulse is often associated with smallness—pulsus durus et parvus; it is then termed corded, wiry, or thready, and this condition is often met with in the earlier stages of inflammatory disease, particularly during the rigor—in endocarditis, and in dangerous inflammations of serous membranes—and experimentally, the thready pulse has been produced by division of the pneumo-gastric nerves.

Dr. Sanderson describes this pulse as follows:—"When the pulse is small and hard, as during the rigor at the outset of acute diseases, and in certain dangerous forms of carditis, the expansion of the radial artery is sudden and of short duration; the suddenness of the movement not depending upon the rapidity with which the arteries empty themselves by the capillaries, but on the violence with which the heart itself contract. In this form of pulse there is no second beat. The explanation is clear: the difference between the arterial and venous pressure is so considerable, and the range of variation in the peripheral arteries so limited, that no perceptible diastolic retardation takes place in the capillaries, and consequently no second expansion."

The hard pulse is seldom associated with largeness; the nearest approach to the hard full pulse—pulsus magnum et durus—is the strong full pulse of laminitis. It may, however, depend upon hypertrophy of the left ventricle of the heart, and be present independently of any inflammatory disease. When the pulse is very hard, the lateral displacement of the submaxillary artery is very apparent; it is then called by veterinarians a hard rolling pulse.
The soft pulse.—Of this kind of pulse several varieties are described. In the small soft pulse, towards the close of progressive exhaustive diseases, the impulse of the heart is slight, the tension of the arteries diminished, and the volume of blood small. In some cases of anemia, however, or of slow action of the heart, or of great relaxation of the arterial coats, or of these conditions combined, there may be a soft full yet feeble pulse. It is readily known by the feebleness of the impulse, and by the artery yielding readily to pressure.
The double pulse.—This pulse is occasionally present in haemo-albuminuria (red water) in cows, and in purpura in the horse. It denotes, according to Dr. Sanderson, that condition of the circulation in which arterial pressure is diminished, while the venous is increased, and that the capillary current, instead of being constant in its rate of movement, is markedly accelerated during the diastole, and retarded during the diastolic interval. In the undulatory double pulse of typhus, says Dr. Sanderson, the intensity and suddenness of the second expansion appears nearly as great as the first; the explanation being, that in this condition the contractions of the heart are extremely feeble, the arterial pressure being so low that the progressive movement of the blood ceases entirely in the capillaries during the diastolic interval.

The strength of the pulse depends chiefly upon the force with which the ventricles contract; in some measure upon the tonicity of the arteries, and upon the volume of the blood. In order to have a strong pulse there must be vigour of impulse, steady resistance to pressure, and a certain degree of fullness. There may be a sharp, forcible beat; but if this is not sustained by a certain amount of subsequent pressure, it indicates irritation rather than energy. A very contracted pulse, however sharp the impulse, cannot be called a strong one. A strong pulse is considered a sign of a sthenic or vigorous state of the system. But it is not invariably so, for hypertrophy of the heart will give strength to the pulse, even though the general powers of the animal be weak.

Weakness of the pulse.—In order to have a weak pulse it is essential that the impulse be slight, the tonicity of the arteries diminished, and the volume small. In some cases, however, it will be found, if there be a slow action of the heart, or great relaxation of the arterial coats, that there will be a full, and at the same time a feeble pulse. It is important not to confound this with strength.

The venous pulse.—Pulsation of the veins is often seen in the jugulars of the ox, especially during rumination, and seems to be quite compatible with health. If the head or neck of the horse be extended, there will generally be an appearance of a jugular pulse. This, however, arises from the beating of the carotida, which is made visible by the parts being tensely
PATHOLOGY.

drawn and pressed together. When a true venous pulse exists independent of heart disease, it is due to the veins filling when the ventricles of the heart contract, and the sudden closing of the auriculo-ventricular valves. It is supposed that there is no actual reflux of blood, but a sudden arrestment of its flow into the right ventricle.

In some forms of heart disease the jugular pulse becomes a diagnostic symptom.—(See Diseases of the Heart.)

SYMPTOMS CONNECTED WITH THE RESPIRATORY FUNCTIONS.

The respiratory movements may be quickened, difficult or laborious, wheezing, roaring, stertorous, spasmodic or convulsive, irregular, slow, thoracic or abdominal; and be attended with such signs as sneezing, coughing, sighing, or yawning. The breath may be hot, as in pneumonia, fever, &c., and cool or cold, as in cases of great prostration; fetid, as in gangrene and abscesses of the lungs, or in nasal gleet arising from diseased bones or teeth. The matters discharged from the air passages are also signs of great value, as blood, pus, mucus, or a mixture of all of them.

(a.) Quickened breathing.—Rapidity of the respiratory movements, although present in many diseases, is easily produced by any cause which accelerates the circulation of the blood, and is generally proportioned to the rapidity of the circulation, and the corresponding need of change in the blood. Thus, exercise, which accelerates the circulation and changes of the blood, also augments the respiratory movements.

(b.) Difficulty of respiration (dyspnoea) is a prominent symptom of disease, and may depend upon various causes. In inflammation of the lungs, or pleurisy, there are many circumstances in operation which impede the respiratory movements—as pain, or exudation into the substance of the lungs or cavity of the chest, which mechanically resists the entrance of air into the lungs. Diseases of the larynx or trachea, by diminishing their calibre, are generally associated with extreme dyspnoea, and with sounds, such as roaring or whistling, which furnish pathognomonic signs of the seat of the disease.

Difficulty of breathing, when not accompanied by certain sounds detectable by auscultation, if not sufficiently loud to be
GENERAL SYMPTOMS OF DISEASE.

heard at a slight distance from the animal, is not, however, to be regarded as symptomatic of disease of the respiratory organs only, for in many acute diseases the breathing not only becomes quickened, but laboured and difficult to an extreme degree.

Difficult breathing must always be regarded as a symptom of importance, not only as being diagnostic of certain diseases, but as indicating grave alterations in the condition of the blood or in the functions of the nervous system. Diseases are also seriously aggravated, and a tendency to a fatal termination, owing to the non-oxidation of the blood, is augmented by difficult breathing.

(c.) Sertorous breathing (Snoring).—This arises from a relaxed state of the velum palati, and is a symptom of brain disease. So long as the respiratory movements are strong and frequent, it does not indicate immediate danger, but when the respiratory powers are impaired, the movements slow—that of inspiration delayed, and then performed with a sudden noise and a jerking effort, and the susceptibility to outward impressions diminished—surtorous breathing is a symptom of the near approach of death. Snoring, so common an accomplishment in the human being during sleep, is but rarely so in the lower animals.

(d.) Abdominal breathing, or respiratory movements performed with the ribs fixed as much as possible, owing to pain or mechanical obstruction in the chest, is a symptom of pleurisy, hydro-thorax, and pleurodynia.

(e.) Thoracic breathing is that in which the abdominal muscles are prevented from participating to their natural extent in the performance of the respiratory movements. This condition is dependent upon abdominal tumours of great magnitude, ascites, tympanitis, or acute abdominal—peritoneal—pain.

(f.) Irregular breathing is that condition where there is a want of harmonious correspondence between the inspiratory and expiratory movements, and is seen in the disease which is commonly known as "broken wind." The inspiratory movement in this affection is performed quickly and with a jerky effort, whilst the expiratory is performed slowly and with a double action, more particularly of the abdominal muscles. Irregular breathing often becomes spasmodic or convulsive during the paroxysms of the disease.—(See Broken Wind.)

Of the phenomena and sounds which attend the respiratory
functions besides those already mentioned, the act of coughing and the varieties of cough demand our careful attention.

A cough is a violent spasmodic action, and the sound is produced by a sudden and forcible expiration, preceded by a firm closure of the glottis; and is for the most part an involuntary effort to remove some source of irritation from the lungs, trachea, or larynx.

The varieties of cough which are met with in veterinary practice are denominated moist, dry, short, hacking, violent, spasmodic, the broken-winded cough, and the cough of the roarer.

The moist cough attends cattarrh, bronchitis, and other diseases where the secretion of the mucous follicles of the air passages is increased.

The dry cough indicates a non-secretory condition of the air passages, and is usually present during the early stages of cattarrhal affections. In pleurisy the dry cough remains throughout the disease; it is also painful, short, and hacking, from the pain which the forcible expiratory movement causes the animal to feel. The dry cough has several modifications from that of broken wind, where it is a miserable apology for a cough, to the loud paroxysmal cough, caused by the irritation of teething, and which may be properly named the dental cough, and the hollow, sepulchral cough of the roarer. Cough does not always arise from direct irritation of the air passages, lungs, or pleura, for we often find an animal coughs when suffering from indigestion, worms in the intestinal canal, diseases of the liver, &c. These sympathetic coughs are always characterised by dryness.

THE SYMPTOMS AFFORDED BY THE SECRETIONS.

The secretions may be either diminished, increased, or perverted. In the early stages of inflammatory disease of a secretory organ, its secretory function becomes diminished. Thus, in the first stages of pleurisy the surfaces of the serous membrane are dry and rub against each other, producing the "friction sound;" but as the disease advances some of the natural fluid secretion of the membrane, along with a quantity of inflammatory products in a fluid state, is thrown out, and the surface, which was dry, becomes unnaturally moist. The same changes occur when a mucous membrane or a gland is inflamed. In the febrile state
there is occasionally a diminution of all the secretions, but this
can only continue for a short time, as some particular organ, the
bowels, kidneys, or skin, is excited to increased action by the
presence of effete materials in the blood, and its secretion thus
increased, while those of the rest are diminished. General
increase of the secretions is scarcely possible, and much more
frequently the increase, like the diminution, is confined to one
or more secretory organs. Excessive and exhaustive secretions
are termed colliquative.

Perversion of the secretory functions is characterised by an
alteration in the character of the secreted materials. The pro-
ducts of secretion are sometimes wholly changed in character
from those of the same organ in health, becoming excessively
irritant, and yielding evidence to chemical re-agents of the
presence of new constituents. In some instances, again, one
secretory organ will perform the function of another, as when
biliary matters are excreted by the kidneys when the liver
ceases to act.

SYMPTOMS BELONGING TO THE CALORIFIC FUNCTIONS.

The animal body is so constituted as to be able to bear great
extremes of heat and cold, and be yet in itself never greatly
above or below the mean standard of health—never greatly
above, and never much below, until vitality has ceased, or has
been so far reduced as to have surrendered the body to the
operation of surrounding influences.

The mean temperature of the body in those internal parts
which are most easily accessible—as the mouth and rectum—
may be estimated at from 99° to 102° F. In thirty-four healthy
horses, all under the same conditions, the temperature was found
to be under 101° in ten; 102.2° in one; and 101.2° to 101.8° in
twenty-one. In young animals the temperature is commonly
about 102°, but in very old ones I have seen it as low as 96°.
The external parts of the body become lowered in temperature
the farther they are removed from the centre, and are liable to
much variation from the state of the surrounding atmosphere.

The method of ascertaining the temperature of the body in the
lower animals is by introducing a properly registered thermometer
into the rectum. The practice of thus measuring the changes of
the temperature of the animal body has now made progress in veterinary medicine, and is considered of great importance as an aid to diagnosis and prognosis. It has been advocated by clinical teachers since 1754, when Antonius de Haen, of the Hospital of Vienna, impressed his pupils with the necessity of attending to the temperature of the body in disease, as measured by a thermometer, instead of being judged by the hand. He showed that even in the cold stage of ague, with the teeth chattering and the body shivering, the temperature of the blood is rapidly rising, although the pallid skin may be cooler than usual, its supply of blood being diminished by the contraction of its vessels.

The production of animal heat is due to certain chemical and vital changes, which are continually taking place in the body; and consist in the absorption of oxygen by the pulmonary capillaries, the combination of that oxygen with the carbon and hydrogen derived from the disintegration of animal tissues, and from certain elements of the food which have not been converted into tissue. This combination of oxygen, or oxidation, not only takes place in the blood, which may be looked upon as a fluid tissue, but in the tissue cells of all parts of the body, the animal heat being thus maintained by the natural changes which are essential to a healthy condition.

The oxidation and natural decay of the tissues, the process by which they are rendered fluid and fitted for absorption, has been termed the secondary digestion, and is thus described by Bennett:—"Growth having been effected, it is necessary that the particles of the tissues which have fulfilled their function and are worn out should be removed to give place to new ones. This constitutes the so-called secondary digestion,—that is, in the same way that a piece of food, say flesh, is broken down, rendered molecular and fluid, and absorbed into the blood to add bulk to the frame, so is our own living flesh constantly breaking down, rendered molecular and fluid, and absorbed into the blood, to be finally thrown out of the system. Thus the blood receives matter from two sources, the primary and secondary digestions; and is continually giving off matter in two directions, one to build up the tissues and form the secretions, the other to produce the excretions."—(Bennett's Clinical Lectures.)

In many diseases this secondary digestion or metamorphosis of tissues, which is mainly due to their oxidation, is abnormally
increased, and the animal heat unnaturally elevated, and if continued for some time, indicates the existence of the febrile condition. The tissues are rapidly consumed, the blood becomes charged with the effete products resulting from the metamorphosis; the appetite being at the same time impaired, the animal becomes more or less rapidly emaciated, and if the abnormal process be not arrested, naturally or otherwise, finally dies.

The determination of abnormal heat in disease has a very great importance, and to detect it practitioners have been in the habit of placing their hand to the skin, and their fingers within the mouth of the patient; but the method of measuring the heat by the thermometer holds a highly important position, not only in cases of illness where the symptoms are apparent, but more particularly in the incubative stages of such diseases as glanders, pleuro-pneumonia-bovina, rinderpest, and other contagious or infectious ailments. Here the early recognition of disease plays an important part in preventing the development and propagation of such maladies, and depends much upon the use of a delicate thermometer. When an outbreak of such diseases as pleuro-pneumonia-bovina or glanders occurs, it is very possible that out of a large herd of cattle or stud of horses but one or two may present any appreciable signs of disease, all the rest remaining apparently healthy; but although they may not present any signs of disease, it does not follow that they are not tainted with the malady in its incubative stage. It must not, however, be supposed that elevation of temperature is diagnostic of any particular disease; it merely indicates the febrile condition, which of itself may be due to a great variety of causes, external and internal, specific and non-specific. Some practitioners are so expert as to diagnose even the incubative stages of pleuro-pneumonia, by placing their fingers in the mouth of the animal, and, from the elevated temperature so felt, be able at once to give an opinion as to the probabilities of the animal being affected, provided always that the disease has already attacked others in the herd. If it be possible to do this by the mere touch, how much more certain and satisfactory will it be, by means of a delicate instrument, to measure the degrees of temperature, and give an opinion based upon conclusions derived from an exact admeasurement.

In glanders and pleuro-pneumonia, the two contagious diseases
which the veterinarian is most likely to be asked to pronounce an opinion upon, now that rinderpest is so safely guarded, the examination of all the animals which have been herded or stalled with those labouring under this disease should be systematically made, and all those presenting an elevation of temperature of from two to three degrees should at once be isolated, and looked upon with suspicion, until time proves whether they are suffering from the malady or not. Nothing can be lost by this, but much may be gained, the most important gain being the destruction of the centres of contagion, and the preservation of the remaining stud or herd; for when an animal is kept mixed with others until the disease be more fully developed, it remains there as a generator of contagious material, and thus propagates the disease over the whole number.

The best thermometer for the purpose is a straight instrument with a registered index. Such an instrument can be removed and read when convenient, for the index, being fixed in the stem, will denote the height to which the column of mercury has been raised. I find it desirable to keep the instrument in the rectum for about three minutes, and to make two observations, and if the two observations correspond, to remain satisfied with its correctness. The pocket thermometer invented by Professor Brown is very convenient and handy, and is specially recommended to the veterinarian.
CHAPTER V.

PATHOLOGY—continued.

MORBID ELEMENTARY PRODUCTS—COMPLEX VITAL PROCESSES Whose PHENOMENA CONSTITUTE DISEASE.

The effects of disease, when they can be rendered obvious by dissections, by the application of various instruments, such as the microscope, and of chemical re-agents, are found to consist for the most part of—

1. Transformations in the elementary textures of the body generally, and altered conditions of the fluids.

2. The presence of new formations foreign to the normal condition of an organ or system of organs.

3. Change in the position or form of some of the organs or parts of organs.

4. Deposits in and around the elementary parts of tissues, or changes of a degenerative or retrograde kind in them. (See Atken’s Science and Practice of Medicine.)

Anatomical investigations of morbid parts, conducted with the aid of the microscope and other instruments of research, show that the material of which their substance is made up is of very various structure, sometimes combined in forms of one kind throughout, and sometimes varied by the development and combination of many elementary forms, more or less solid, soft, or fluid.

An analysis of the morbid material, carried as far as scientific means at present enable us, shows that the elementary conditions in which morbid products are found may be described as follows:—

1. Fluid matter and hyaline substance, more or less soft.
2. Simple elementary forms of the nature of deposits, sometimes of a mineral or inorganic character; e.g. (a.) amorphous granules; (b.) crystalline structures in a granular state.

3. Simple but organised products capable of growth; e.g. (c.) granules; (d.) compound corpuscles; (e.) simple cells; (d.) fibres.

The various appearances and conditions which these simple forms may assume in disease, as well as the functional states with which they are frequently associated, lead to a further enumeration and classification of morbid elementary products, as well as of more complex disease processes, as below.

**MORBID ELEMENTARY PRODUCTS.**

I. **Exudations more or less soft, semi-fluid or fluid, and formed of**—

(a.) Germinal plastic and formed material, which has sometimes been called blastema, coagulable lymph, false membrane, or fibrin, as seen adhering to free surfaces.

(b.) Aqueous matter, as seen in the morbid state termed dropsy, and cedems of parts.

(c.) Gaseous exudations, as seen in the various forms of pneumatosis.

II. **Exudations more or less consolidated, and consisting of**—

(a.) Molecular or granular material, from 1⁄8 of a line to an immeasurably small size, and consisting chiefly of the simple forms of—

(1.) Fatty molecules of granules.

(2.) Forms of an organic kind capable of growth, and invariably taking origin from a pre-existing structure.

(3.) Deposits of an inorganic kind, generally calcareous salts.

(4.) Pigment granules.

(b.) Coagulable compounds, resisting the action of most reagents, such as are seen in the elements of tubercle, scrofula, oleo-albuminous formations.

(c.) Exudations of a transitional nature, organised, capable of
growth, which may become vascular, growing from pre-existing structures, and composed of—
(1.) Consolidated homogeneous material, passing to
(2.) A fibrillloid arrangement of the molecular or granular
particles composing connective substance, and a subsequent formation of fibres in it or from it.
(3.) The formation of pyoïd cells, and of fibro-plastic or
connective tissue cells, passing into fusiform cells and
fibres as the material becomes consolidated.
(4.) The formation or exudation of fluid matter holding
pus, or other more compound cells.

III. Growths and exudations of a more or less specific kind.
(a.) Lymph of small-pox and cow-pox.
(b.) Matter of glanders, malignant pustule, and of the
plague.
(c.) Fluids of infecting chancre, and of some forms of
secondary syphilitic lesions.
(d.) Material of tubercle and acrofula.
(e.) Material of cancer.
(f.) Growth of Peyer's glands during typhoid fever.
(g.) The growth of Peyer's glands in cases of cholera.
(h.) Melanotic or pigmentary germs.

IV. Material of a complex kind.
(a.) Media of repair and reproduction of injured or lost
parts—substance of granulations and cicatrices.
(b.) Hypertrophy of parts.
(c.) Tumours, { Innocent.
{ Malignant.
(d.) Concretions.

V. Parasitic formations.

VI. Organic germs—such as Bacilli.

COMPLEX VITAL PROCESSES WHOSE PHENOMENA, MORE OR LESS
COMBINED, CONSTITUTE DISEASE.

(1.) Fever—Pyrexia. (5.) Depression.
(2.) Inflammation. (6.) Atrophy.
(3.) Irritation. (7.) Degeneration.
(4.) Congestion.
Such a classification as the above is merely intended to bring before the student at a glance the variety of morbid material which is concerned in the expression of many of these phenomena seen in the course of disease, the distinctions made being mainly based on structural analysis.—(Aitken's Science and Practice of Medicine.)

It was formerly a much debated question whether diseases had their principal seat in the fluids or solids of the body. At the present time the purely solidist, as well as the purely humoral principles, may be said to have died a natural death, and we can only wonder how men could have advocated exclusively one view or the other, and refused to allow that both solids and fluids had their share in the production of morbid phenomena. That many diseases are caused by the presence of a morbid material in the blood, which of itself is perhaps the first to be modified, there can be no doubt; at the same time it cannot be denied that the tissue plays a most important part in the various pathological processes which constitute disease. In pleuro-pneumonia contagiosa, for example, the blood is undoubtedly the recipient of the contagium; but it would be erroneous to suppose that the operation of the morbid material was confined to the blood alone, and that the exudation found on the pleura and in the parenchyma of the lungs was a mere precipitation of a product formed within the blood-vessels. In reality, the poison, though taken by the blood to all parts of the animal frame, is limited in its effects to the tissues of the lungs and pleura, and, like a medicine which has special affinities, passes harmlessly over all the other organs and structures of the body. In such an instance the blood contains the cause of the disease, whilst the solids of the parts affected are the seats of the diseased processes. So it may truly be said that both fluids and solids are alike the seat of the disease, that they are mutually dependent one upon the other, that the solids are almost of necessity liable to be affected by the fluids, and the fluids by the solids.

In some diseases it is found impossible, with the aid of the most exact instruments, to detect any structural change, or the presence of any of the morbid products already enumerated. Such diseases are termed functional, whilst those in which an alteration of the part can be detected are called structural or organic diseases.

Functional derangement is undoubtedly due to an alteration
in the nutrition of the part, and is a condition which cannot exist for any length of time without the occurrence of an organic or structural change. The most familiar functional derangements are the conditions of increased sensitiveness, irritability, and contractility of muscular tissue, and tonicity, which is a modification of contractility,—termed passive, in opposition to active contractility, by Mr. Bowman. Of excessive contractility we have examples in spasmodic colic and in chorea, where the contractions are sudden, and alternate with sudden relaxations. Contractions of this kind are termed clonic spasms; and of excessive tonicity, or tonic spasms, we have examples in the arteries, when the pulse indicates a hard, unyielding condition of the arterial walls; in cramp of some of the voluntary muscles, and, in an extreme degree, in tetanus.

Opposed to the above conditions we have loss of sensibility, anesthesia, and paralysis.
CHAPTER VI.

PATHOLOGY—continued.

ATROPHY AND DEGENERATIONS OF TISSUE.

ATROPHY.

Atrophy implies a wasting of a part, arising from a diminution in the size or a decrease in the number of the tissue elements of which that part is composed. Atrophy of the normal structure of a part may take place without any apparent diminution, but may be coincident even with an increase in size. Thus, the fibres of a muscle may be atrophied, whilst its whole bulk is increased by an interstitial exudation, which, pressing upon the true sarcoous elements, causes their wasting and absorption. Again, a glandular organ may be apparently enlarged, whilst its true gland structures are considerably lessened.

Atrophy is divided into simple and numerical atrophy. Simple atrophy is applied to the diminution in the size of the tissue elements, and numerical atrophy to the process by which their number is diminished. The two varieties are often associated. Simple atrophy may, however, exist independently, but the numerical never occurs without the simple. Atrophy is not always a morbid process, as, for example, in the disappearance of the thymus gland, which is large in the fetus, and is removed shortly after the birth of the animal.

Simple atrophy is well shown in ordinary emaciation, in which fat disappears from the subcutaneous adipose tissue. Here there is no destruction of the fat cells, but simply an absorption of some of their contents, by which their size becomes more or less diminished. The same process may take place in the cells of glandular organs, and so produce a diminution in the size of
the whole organ. Muscular tissue also wastes in the same way, by a decrease in the size of the primitive fasciculi, as exemplified in the voluntary muscles and the heart.

Numerical atrophy resembles gangrene in some respects, for death of the part is common to both; but they differ in the following points. In gangrene, tracts of tissue are affected. It results from some sudden arrest of nutrition, and a gangrenous mass remains at the termination of the process, in such a condition that the structure can be usually recognised; whereas in necrobiosis the change is a molecular one, with gradual exhaustion of the vital power, a molecular disintegration and destruction of elements, so that at the termination of the process all that remains is a glandular debris, in which no trace of the natural structure of the part can be discovered. This form of atrophy is of much greater importance than the simple; for in the simple the elements of the part continue to exist, and repair can be effected without any new formation; whilst in the numerical, restitution is only possible by the production of new elements.

Inactivity of a part, obstruction of its blood-vessels, failure of its own vital energy, continued pressure upon its surface, and the process of inflammation, are all well-known causes of atrophy. A muscle, if unused, becomes small and pale, and its tissue degenerates. This atrophy of muscular tissue from diminished activity is often seen in the horse. For example, a horse is chronically lame in a foot. In consequence of the pain felt by the animal, the limb is kept in a state of quietude and repose; the animal moves it as little as possible. The muscles, thus kept inactive, diminish in size, and the whole limb seems to shrink. If the cause of the lameness be removed, and the limb regain its former activity, the wasted muscles are restored to their natural condition and strength. Paralysis also leads to shrinking of a limb; and it is recorded that injury to a trunk of the sympathetic nerve will produce the same condition without impairment of motion or sensibility. Atrophy and softening may result from the ingestion of improper food. Majendie kept animals upon food containing no nitrogen and incapable of supplying sufficient nourishment; and one curious result was

1 The term necrobiosis is applied by Virchow to the destruction of histological elements, which occurs both in atrophy and degeneration.
atrophy and softening of the cornea, which melted down and disappeared. Again, the stomach may be softened and its mucous membrane dissolved by the action of the gastric juice. This occurs in the dead body only, although it has been mistaken for the effects of disease. Atrophy may also be caused by the action of medicinal substances, such as mercury, iodine, bromine, and the alkalies. Iodine and mercury are said to exercise an influence on the lymphatic system, and bromine upon the generative organs. Bone is sometimes atrophied both in the horse and in the ox. This atrophy of bone is attended by a diminution in its weight, but the size of the bones in the specimen which I possess does not seem to be altered. The compact tissue is thin, the cancelli have mostly disappeared, the medullary canal, filled with a lardaceous looking fat, extends from one extremity of the bone to the other, and the periosteal surface of the bone presents a more or less cribiform appearance.

The various structures of which an organ is composed may suffer from atrophy. Some, however, do so more than others. The fibrous tissue generally increases in amount. In glands, the secretory cells are the first to suffer. They become small, and often granular, from the presence of oil globules. In muscles, the fasciculi become smaller, and lose their transverse strie, and finally the whole contents of the sarcolemma may be absorbed, and leave nothing but fibrous tissue, which may or may not be transformed into fat.

DEGENERATIONS OF TISSUE.

The wellbeing of every part depends upon the nutritive processes being actively performed by its cells, and upon a due supply of properly constituted plasma—formative material, germinal matter—protoplasm (Huxley), bioplasm (Beale)—being conveyed to it by its vessels. The formative process—nutrition—is performed by the cell, which is the seat of nutrition and function, each individual cell being in itself an independent organism, endowed with all the properties of active life. Various opinions are held as to the constitution of cells. Some writers maintain that a cell is composed of a cell wall, enclosing a cavity containing a nucleus and fluid contents (Schwann, Remak, Virchow, &c.); others state that the existence of a cell
wall is in many cases non-evident, more particularly in embryonic cells, in those of many rapidly growing new formations, blood corpuscles, pus, and mucous; that a cell is a small mass of matter enclosing a nucleus, and that the existence of a cell wall is due to a degenerative process going on in the outer layers of the mass. Thus Beale says, "A cell of epithelium consists of bioplasm or bioplasmatic matter, surrounded by formed non-living matter, which was once in the bioplasmic state. In the same way an oval yeast particle consists of the bioplasm, with an envelope of formed material, which has resulted from changes occurring when particles upon the surface of the bioplasm died."

Brücke, Stricker, and others consider that the existence of a nucleus is not essential to the constitution of a cell; and they base their conclusions upon the fact that in some of the lowest forms of life cells occur which show no trace of nuclei. Notwithstanding this conclusion—that a cell is an elementary organism capable of exhibiting all the phenomena of life—the nucleus is exceedingly constant in all cells, and presents fewer varieties in form and size than the cells themselves; is spherical or oval in shape, and often contains one or more minute round or angular bodies—the nucleoli; offers greater resistance to chemical reagents than the other constituents of the cell, and in disease often remains after these have been destroyed. It seems to be structurally homogeneous or slightly granular, is more deeply stained by carmine—a property peculiar to formative material—and is in some cases invested by a limiting membrane.

The cell contents have the power of spontaneous movement, and these, as well as the alterations in form characteristic of young cells, are due to the germinal living matter, which is probably the sole seat of the nutritive and formative power of the cell. This germinal matter, or bioplasm, differs in volume and consistence in different cells, and in the same cell at different times. It is capable of imbibing and giving up fluids, and of undergoing corresponding alterations in volume.

It is now generally accepted that every cell originates from a pre-existing cell, that tissue is formed by the natural formation and growth of cells, and that the deviations from this process constitute the basis of every pathological change.

The multiplication of cells may take place—1st. By simple division; 2d. By budding—gemmation; and 3d. By the forma-
tion of new cells within the parent cell—endogenous growth. The multiplication by simple division is the most frequent method. The cell divides and forms two cells, each of which divides again and forms two more, and so on. In nucleated cells the nucleus generally divides first.

In multiplication by budding, a small portion of the germinal matter projects from the cell, and becomes detached by constriction at its base, and forms a new cell.

Endogenous multiplication occurs in cells with an indurated outer layer—dense cell wall—as in some varieties of epithelium. The germinal matter divides within the membrane, and forms a number of new cells. We have thus a parent cell enclosing a brood of young cells, of necessity smaller than the parent cell, which are subsequently liberated by solution of the parent cell wall, or escape by their own inherent power of movement.

Nutrition may then be said to be dependent on two things:—

1st. Upon a due supply of plasma; and 2nd. Upon the appropriation and elaboration of the plasma by the cellular elements having vital properties, and possessing within themselves the powers of growth and reproduction.

When nutrition becomes absolutely arrested, death of the part where such arrestment occurs is the consequence. When the arrest of nutrition is general, the whole body dies; when it is local, gangrene or necrosis is the result. These two latter conditions having been already described in my work on Veterinary Surgery, I will pass on to those morbid conditions which are dependent on impairment of nutrition, namely, Atrophy and Degenerations.
CHAPTER VII

PATHOLOGY—continued.

ATROPHY AND DEGENERATIONS OF TISSUE—continued.

DEGENERATIONS.

Atrophy and Degeneration resemble one another, in so far that, in both, nutrition is impaired and function interfered with. In atrophy the part may be said to be altered in quantity, the waste of the tissue being in excess of the formation of new material. In degeneration, however, the structure of the part is altered in quality, a new formation being present in the tissues, impairing their vitality and interfering with their functional activity.

The degenerations are divided into two classes, namely, the Metamorphoses and the Infiltrations.

THE METAMORPHOSES.

These consist of an alteration in the albuminoid structures, whereby they are changed into new materials, with disappearance of the elements of the tissue proper, softening of the intercellular substance, and loss of function. The metamorphoses are the fatty, calcareous, mucoid, colloidal, pigmentary, and amyloid degenerations.

FATTY DEGENERATION.

This is the most common of the degenerations, and consists in the transformation of the albuminoid constituents into fat, or rather in the replacement of the healthy tissues of a part by drops or molecules of an oily nature, which appear as
minute granules within the cells of the tissues. A muscular fibre thus affected shows that the sarcous elements, the real contractile tissue, within the sarcolemma, are replaced by shining oil particles, so that the contractile power of such fibre is destroyed. These oil granules, when examined microscopically, present a sharp contour, a dark colour, and strongly refract light. They are soluble in ether; and as they increase, they, by coalescence, sometimes form distinct drops of fat, but usually they retain their granular form. The cells, however, which contain them increase in size and become globular in shape, the nucleus and cell wall are destroyed, and the cell transformed into a mass of fat. The destruction of the cell is an essential element in fatty degeneration, and distinguishes it from fatty infiltration, where the cells, within which the fat accumulates, still remain.

This pathological process is very similar to some of the physiological ones. Thus, in the formation of milk, the cells lining the lobuli of the mammary gland multiply abundantly, and are converted into fat; then they break up, and constitute the creamy particles (corpuscles) of the milk. The corpuscles thus formed are pushed forward in the ducts by the formation of new cells, which in their turn undergo the degenerative process, and in this manner a continuous formation and destruction of cells take place.

Fatty degeneration is clearly a kind of atrophy, but is not identical with the simple form, for it may be seen, in degeneration of the heart more particularly, that the muscular fibres may be atrophied with loss of their transverse striae, and yet contain not a single drop of oil.

When much tissue is affected, the change can be readily distinguished with the naked eye by the yellowish white appearance, and by a diminution in consistence and elasticity.

The parts most commonly affected by the fatty metamorphosis in the horse are the laryngeal muscles—producing the disease which is so well known by the term "roaring,"—the voluntary muscles, particularly those of the shoulder, the coats of the
arteries, the walls of the heart, and the cartilaginous basis of bones.

**Causes of fatty degeneration.**—All influences which interfere with the nutrition of a part may cause this change. Indeed fatty degeneration may be looked upon as an advanced stage of atrophy, and depending upon the same causes—namely, diminished supply of blood, inflammation, decreased functional activity, and diminished nervous influence. Rapid growth is also a cause of degeneration of a part. Thus a rapidly growing tumour is liable to softening and degeneration, as seen in the softening of the central portions of cancer, &c.; and lastly, old age, by impairing the vital activity, may cause degenerations and softening of various parts of the economy.

The formation of the fat depends upon changes in the tissue itself, and not upon the deposit of it from without; that is to say, upon a conversion of the albuminous constituents of the tissue into fat, in a manner similar to that process which occurs after death, when from spontaneous decomposition a peculiar kind of fat, named adipocere, is formed out of the albuminoid tissues.

The fatty metamorphosis may be looked upon as a salutary change when it occurs in new formations, in thrombi, and in inflammatory exudates. Indeed it is only through the occurrence of this change that they are rendered liquid and capable of absorption.

Various changes may take place in the fatty degenerated material. Sometimes it gradually dries up into a yellow substance resembling cheese. This process is termed caseation, and appears to be owing to a natural dryness of the tissue, and is most frequent in parts which are not very vascular, or in those where the vessels are occluded. This process of caseation is most frequently seen to take place in new formations, composed of closely crowded cellular elements, such as tubercle, growths in the lymphatic glands, &c.; and in them the material, after gradually drying up, may become enveloped in a capsule of fibrous tissue, and remain inert in the midst of surrounding structures. These cheesy matters are often met with, particularly in horned cattle, in the lungs, pleura, and peritoneum, and are apt to cause considerable confusion, as it has been the custom to look upon all cheesy matter as tubercular. To conclude that these cheesy masses
are always tubercular is erroneous. In themselves, they merely indicate that the growth has undergone a fatty metamorphosis, but they do not furnish any evidence of any one particular form of growth. As a result of pleuro-pneumonia, they merely indicate that the exudate has undergone this form of metamorphosis, not that there has been a tubercular growth. At a subsequent period caseous material may be either calcified, or may become softened, absorbed, tainting the blood-mass, or give rise to the formation of tubercular tumours.

CALCAREOUS DEGENERATION.

Calcareous degeneration or calcification is an advanced stage of caseation, and is chiefly found to take place in masses of caseous material which are enclosed, and isolated from the influence of the external air, and it is a sure evidence that the growth, whatever may be its nature, has been existent for some length of time. Rokitansky considered the earthy materials not so much as new deposits, but as precipitations of salts, principally consisting of the phosphate of lime and magnesia, and carbonate of lime, from their natural combinations with pre-existent animal matters.

Calcareous degeneration does not always depend upon a previously fatty degenerate state of a part, although it often results from such. It may occur under two opposite conditions, namely, when there is an absolute increase of earthy matters in the blood, and the excess deposited in the tissues; and when there is no such increase, the deposition of earthy salts which then takes place being consequent upon some alteration in the tissue itself. The former condition is oftener met with in man than in the lower animals, and results from extensive caries and other degenerative bone diseases, where the lime salts are removed from the bones into the blood, and deposited in other tissues.

In such cases, the calcification affects many organs simultaneously, and it is not an uncommon thing to find the lungs, kidneys, stomach, intestines, liver, and even the dura mater, infiltrated with lime salts. Again, it is found in man that chronic disease of the kidneys leads to calcification of several organs. This is due to the fact that the lime salts, which ought to have been excreted by the kidneys, accumulate in the blood,
and are deposited in those portions of the tissues which immediately surround the blood-vessels.

Calcification is, however, a process most commonly dependent on local causes—depending not upon any undue quantity of lime salts in the blood, but upon a change in the part itself, whereby the salts which are normally held in solution in the blood are deposited in the tissues. This process is often characterised as an ossification, and not without some reason, as the so-called bone cells or lacunae are often found in the calcareous substance; they are, however, imperfectly and irregularly developed. I have one specimen in my possession, presented by Mr. Robertson of Kelso, where very well developed lacunae are found to exist in the calcareous mass. The specimen consists of a bony or calcareous tube surrounding a piece of wood which had been lodged in the inguinal region of a horse for some years. It is a most perfect specimen of the ossification of an exudate, having no connection with a bone.

Calcareous degeneration seems generally to take place in parts whose vitality has been lowered by previous morbid changes, and in degenerating new formations. A part which has become calcified undergoes no further change, but remains as an inert mass: on this account it must be looked upon as a salutary termination of a diseased process. It is thus the most favourable termination to all degenerative diseases, as exemplified in the calcification of many new formations, inflammatory products, tubercle, and atheroma of the arteries.

Eindlich states that the cause of the deposition of the salts in the substance of atrophied tissue is partly owing to the stagnation of the nutritive fluids in the part, owing to which the free carbonic acid, which holds the salts in solution, escapes, in consequence of which they are precipitated; and partly to the non-assimilation of these fluids by the degenerated tissue. The saline matters are seen at first as fine molecules, scattered irregularly through the intercellular substance, and are characterised, when viewed by transmitted light, by their opacity, dark colour, and irregularity of outline. They are soluble in dilute mineral acids, after which the original structure of the part, if not destroyed by previous change, may again be recognised.

"Softening" consists in the liquefaction of the caseous substance, probably owing to some chemical change in its constituents. It
commonly occurs in parts which come in contact with the air." — (Green.) The caseous mass is converted into a thin puriform fluid containing curd-like matter, composed of animal débris, fat, and cholesterine crystals, which, if not absorbed or discharged, may ultimately dry and become calcified.

THE MUCOID AND COLLOID DEGENERATIONS
Are conditions which are rarely met with in the lower animals. The reader is therefore referred to works upon human pathology, more particularly to Green's Pathology and Morbid Anatomy.

Pigmentary Degeneration.
In this process pigment takes the place of the tissue elements, in the same manner as fat or earthy salts in the fatty and calcareous degeneration.
I have witnessed this form of deposit in the lungs of horses. It is, however, of little importance, and I shall merely refer the reader to authorities upon the subject, amongst whom may be mentioned Aitken, Bennett, Virchow, and Green.

Amyloid Degeneration.
This morbid process consists in the transformation of the tissues into a peculiar homogeneous substance, having a relation in some respects to the chemical characters of cellulose or starch.
This degeneration has been long known by medical men under a variety of names, such as the fardaceous, waxy, bacon-like, and albuminoid degeneration. I have met with several cases which presented the physical appearance of this form of disease both in the liver and in the kidneys; but I have only satisfied myself in instance of the character of the morbid product. For an account of the method by which this disease has been investigated, I take the liberty of making the following quotation from Aitken, who, after mentioning a number of names by which the disease has been known, proceeds to say that "Chemistry and micro-chemical investigation have modified the views regarding the nature of the disease, and now and then have led to modifications in the nomenclature. Under this kind of inquisitive
Atrophy and degenerations of tissue.

Investigation it has been described—(1.) By Virchow under the name of 'animal amyloid,' he believing, from the behaviour of the transformed substance with iodine and sulphuric acid, that the substance must be classified with the vegetable carbo-hydrates—cellulose and starch: (2.) Meckel retains the name of 'lardaceous' or 'cholesterine disease,' believing that the essential character of the degeneration consists in the development of a peculiar fatty or lardaceous matter of the nature of cholesterine: (3.) The more extended and definite examinations by Friedrich and Kekulé have shown that the substance of the purest amyloid degeneration more closely resembles the albuminous principles than any other substance we know of; and (4.) Schmidt has arrived at the same conclusion. The question, therefore, is not yet definitely settled as to the exact nature of the substance into which the tissues are transformed in the so-called amyloid degeneration; but the weight of evidence points to its being albumen in some form." The conclusions that the material is allied to albumen are confirmed more recently by Kühne, who, by submitting the amyloid organs to a process of artificial digestion, has completely succeeded in isolating the new material, and has thus been able to determine its albuminous nature. Starch-like bodies (the corpora amylacea) have been discovered in various parts of the body, more especially in the nervous system, the ependyma of the ventricles, the white substance of the brain, the choroid plexus, the optic nerve and retina, and the spinal cord of the aged; and larger varieties of the same bodies in the prostate gland of almost every adult, accumulating here sometimes to such an extent as to form large concretions.

The most characteristic feature of the amyloid substance is its reaction with iodine, and with iodine and sulphuric acid. A solution of iodine applied to the amyloid organ causes the affected portions to change to a deep reddish brown colour, which is not, however, permanent, but gradually passes off, and the part regains its former appearance. If the application of iodine is followed by the cautious addition of sulphuric acid, a blackish blue or violet tint is produced. Great nicety of manipulation is, however, necessary to obtain the reaction of the sulphuric acid.

General characters of tissues which have undergone the amyloid degeneration.—The cut surface of an organ so affected has a
semi-transparent appearance. It feels like a piece of soft wax, or of hard and wax combined.—(Wilks.) It cuts into portions of the most regular shape, with sharp angles and smooth surfaces, and the thinnest possible slices may be removed by a sharp knife for microscopic examination. They are abnormally translucent. Water and alcohol, acids and alkalies, do not produce any change upon the transformed parts, which may be kept for a length of time without decomposition. The organs affected are increased in volume, in solidity, and in weight, absolute and specific. Anemia is predominant; but the colour of the blood, or of tissue, shines through the semi-transparent morbid substance.

Amyloid degeneration is generally widely diffused, so much so, that a constitutional state of ill-health seems associated with its production; and in cases preceded by a local disease, such as caries of a bone, the degeneration may be found in the adjacent lymphatic glands only.—(Billroth.) This is the earliest appearance of the degeneration yet recognised.—(Atkên.)

The amyloid substance almost invariably affects the capillaries and small arteries. Their coats become thickened by the deposit, and at last pellucid, transparent, and hyaline. The deposit then extends into the surrounding tissues, and invades both its cells and intercellular substance. The cells become filled with the amyloid material; they gradually increase in size, become round and regular in shape, their nuclei disappear, and they are finally converted into homogeneous bodies, having a translucent or glistening appearance. The effect of this change in the nutrition is to impair or even destroy the function of the affected organ:—1st. By obstructing its circulation, by diminishing the calibre of small arteries; and 2d. By the pressure of the new material upon its proper substance, whereby secondary atrophic changes are induced. It is important to remember that this form of degeneration is secondary to some serious constitutional disease. It is supposed that it is due to some change in the blood, and that the deposit is in reality an infiltration of an albuminoid or fibrinous substance from the blood into the tissues, which there becomes consolidated. In the human being it is found to succeed chronic suppurative diseases, and the way in which the tissues are affected is as follows:—The change almost invariably commences in the small nutrient blood-vessels, and extends from them to the surrounding parts,
and the general characters of the affection, several organs being simultaneously involved, point to some alteration in the composition of the blood as the cause of the change. In the instance where I succeeded in tracing the nature of the deposit, the horse had been lately bought, suffering at the time from what appeared to the purchaser to be the remains of a cold, sore throat, or strangles. When seen by me, five weeks after purchase, the animal was much emaciated, and presented symptoms of disease of the liver, and was evidently in a dying condition. The post mortem revealed the liver much enlarged, weighing over twenty pounds, and of a glistening, palish yellow colour throughout, the new material being stained by the biliary matters; the kidneys were also enlarged, very solid, pale, and translucent in appearance; and when cut, the surfaces were smooth, bloodless, and glistening. The iodine test was most conclusive. It is important to bear in mind that amyloid disease is essentially chronic in its character, and when deposited to any extent, is a sure sign that the animal has been in ill health for a period extending over many weeks, or even months.

FATTY INFILTRATION.

This essentially differs from fatty degeneration. In degeneration, the fat is derived from a change of the protoplasm itself, leading ultimately to the destruction of the cells of the part. In infiltration, the fat is deposited between, as well as within the cells, where it displaces and obscures the nuclei and protoplasm, but does not destroy them. In degeneration, the fat occurs in a granular form within the cell contents. In infiltration, the fat is deposited as distinct drops, which may gradually increase and coalesce, so that the cells, as in the figure, may be completely filled and distended with it. The functions of the cells are but little impaired by the accumulation, and are restored to their natural condition by the removal of the fat.

Fig. 2.—Fatty infiltration of heart. Large fat cells intermixed with muscular tissue.
Fatty infiltration is due to an increase of oleaginous materials in the blood, which arises from high feeding and want of exercise. It occurs as a physiological process in the fattening of animals, where the connective tissue becomes filled with fat.

In the human being it has been observed that this form of infiltration is occasionally owing to the presence of fat in the blood, arising from its absorption from some particular tissue and its deposition in another: for example, the general emaciation of pulmonary phthisis is sometimes associated with fatty infiltration of the liver. "Why the deposition should take place in certain tissues, and the fat be removed from some and deposited in others, is not known."—(Green.) Fatty infiltration, more particularly of the liver, has occurred in my experience involving legal points of some consequence. In two cases which more particularly occur to me, the animals died within a few days after being purchased. In one case the liver weighed thirty-five pounds, was of an opaque yellowish white colour, its surface smooth, the edges round and thick, doughy to the touch, pitted on pressure, and when cut into, the knife was coated with oil, which oozed from the cut surfaces pretty freely. In the second case, death occurred twelve days after purchase: the liver was not so large as in the former instance, the deposition occurring more as isolated patches than as a general infiltration. In both instances the purchasers succeeded in obtaining a return of the purchase-money. Fatty infiltration is caused by high feeding, more particularly by food containing an excess of the hydrocarbons—such as the oil cakes—and is apt to occur in animals quickly prepared and made fat for sale. It also frequently occurs in very highly fed cart-horses employed for slow work, and often causes death by the liver enlarging to such an extent as to burst its capsule.

Why the liver should suffer from the accumulation of fat, is explained by the fact that when animals are fed on hydrocarbonaceous food, an excess of fat in the blood is the consequence, such fat being, before it is finally disposed of, deposited in the hepatic cells, more particularly in those cells in close contact with the capillaries of the vena portae, at the circumference of the hepatic lobules. This temporary infiltration occurs after every meal, and the fat passes from the cells at the
circumference to those situated more within the liver, then into the blood-vessels, and is finally disposed of, either by being deposited in other tissues, or destroyed in the maintenance of the animal heat.

There is thus a temporary accumulation of fat in the liver, which is gradually removed, and the vitality of the hepatic cells is not impaired. By bearing these facts in mind, we can more readily understand that when an animal is constantly fed on such a diet, the accumulation may be too great to be disposed of or consumed, and that it remains permanently within the hepatic cells, or so long as the animal continues to be so fed and treated, interfering to some extent with the secretory powers of the organ, and rendering it unfit for ordinary work. A liver subjected to the stimulating influences of such food is prone to attacks of congestion, which are occasionally so great as to cause a rupture of Glisson's capsule, and bring on death from haemorrhage. It is well to remember that when a horse is excessively fat, the liver may be in this condition; that there is a possibility of death occurring from congestion or rupture; and that the probabilities of recovery from diseases which may have no immediate connection with the liver itself are much lessened. If, however, the animal be carefully brought into condition, regularly but moderately worked or exercised, and fed on food containing no excess of the hydrocarbons, but rich in nitrogenous materials—such as oats, beans, and hay—the liver cells will be again restored to their normal condition by the absorption of the contained fat.

As a veterinary legal question the matter is of some importance, as horses often die if not cautiously and carefully treated when loaded with fat.

It is well known that a practice prevails in many parts of the country of fattening horses rapidly prior to showing them for sale, by giving them an immoderate quantity of highly carbonaceous or even oleaginous food. To the eye, such animals present all the signs of good health. They are, however, totally unfit for work, and too well does the experienced veterinarian know, that when they are seized by an ordinary attack of disease—such as a cold, influenza, &c.—that the chances of recovery are more remote than they otherwise would be, by the liver and other internal organs being loaded with fat. The ten-
dency to produce fat rather than muscle prevails to a very great extent in this country, encouraged and fostered by our agricultural societies, and by purchasers who buy to "please the eye." The question presents itself—Who is responsible when a horse dies in a few days after purchase, either directly or indirectly from this cause? The buyer or the seller?

Fatty infiltration must be carefully separated from fatty degeneration. Degeneration of normal tissues is at all times a morbid process indicative of chronic disease. Infiltration, on the other hand, is a physiological process depending on well-known causes, and furnishes no evidence of a chronically diseased condition of the organ affected. As an example of the importance of the separation of the two conditions, we will suppose a case analogous to what often happens, of a horse in poor condition—thin—being purchased from the breeder and rapidly fed for sale. Such an one puts on fat quickly, and thrives as well as its purchaser can desire. We will say that it is sold and put to work, and that it dies in the course of a week or two after the second sale. Altogether it has not been out of the hands of the breeder more than two months. Now, the last purchaser naturally looks for restitution to the person from whom he bought it, who, in his turn, may make a claim on the breeder. In many cases the matter is amicably settled by the three interested parties dividing the loss amongst them. Is this just? Decidedly not; and in all such instances the man who sold the horse before the fattening process had been commenced should not be made to suffer, the enlargement of the liver being merely due to an accumulation of fat, and not to any disease; and if one individual is to suffer, let the man who resorted to the forcing system of producing fat be made responsible; or let the loss be divided between him and the man who bought what pleased his eye, and who must have known, or ought to have known, that an animal loaded with fat was unfit for useful purposes. But should an examination reveal that the condition of the liver was due to degeneration, the case is entirely different, for beyond a doubt the disease must have been present prior to the first purchase, and the breeder ought then to be responsible for the whole loss.

Degeneration generally occurs in the aged, and may be associated with general emaciation, and with degeneration of other
NUTRITION INCREASED.

Opposed to the conditions of atrophy and the degenerations, is that of increased nutritive activity, or hypertrophy. In hypertrophy there is an absolute increase of the normal tissues of a part, resulting from an increase in its functional activity.

Hypertrophy, although sometimes depending on disease, is of itself a compensating process, whereby injury from damage to an important organ may be avoided; as, for example, in the thickened condition of the heart in disease of the valves, and in the same condition of that organ when not associated with any disease, but arising from the animal being repeatedly forced to severe trials of strength and endurance, in racing, hunting, &c. In the first instance the hypertrophy of the cardiac walls arises from the necessity of a more powerful contraction for the purpose of overcoming valvular obstruction, and sending a due supply of blood to the various organs of the body, and in the other case of contracting powerfully to attain the same end, during repeated and severe exercise.

As a physiological process, hypertrophy of muscular tissue is produced by the process of training, where the muscles of the whole body are enlarged, strengthened, and made capable of performing extraordinary feats of strength and endurance. Who can fail to see in a well-trained racehorse the muscles standing, as it were, prominently one from another about the quarters and thighs, "hard as iron" to the touch, and giving the animal an appearance of being thin and poor. The appearance of thinness is the result of the great prominence of each individual muscle, of increase in their volume and weight, and an extraordinary healthy tonicity.

"The cause of real hypertrophy seems to be always the increased exertion of the organ; more than usual effort is demanded of it, and according to the law of the circulation, which we have noticed, more blood flows to the part than usual. This, if the organ be in a healthy state, not only supplies its waste, but furnishes material for increase and development. The heart in various diseased states of its valves, the urinary bladder in stric-
ture of the urethra, the remaining kidney when one is destroyed, the muscles, and even the solid bones themselves, when long and actively exercised, afford excellent examples of true hypertrophy."—(C. Handfield Jones.)

Whilst increased nutritive activity may lead to hypertrophy, or an increase of normal tissue only, it may, on the other hand, lead to the production of new materials in a part, to which the name of new formations—tumours—are given. These have been, to some extent, described in my work on Veterinary Surgery.
CHAPTER VIII
PATHOLOGY—continued.

CHANGES IN THE BLOOD.

Healthy Blood, when it can be seen flowing in the vessels of a living part, appears as a colourless fluid—the liquor sanguinis—containing minute solid particles—the blood globules—of which the greater part are red, and the remainder colourless or white.

Analyses of blood show that it is composed of, in 1000 parts—

\[
\begin{align*}
\text{Water,} & \quad 784^1 \\
\text{Red corpuscles,} & \quad 131^1 \\
\text{Albumen,} & \quad 70^1 \\
\text{Saline matters,} & \quad 6.03 \\
\text{Extractive matters,} & \quad 6.77 \\
\text{Fibrin,} & \quad 2.2
\end{align*}
\]

\[1000:00\]

The above constituents being proportioned as follows:

\[
\begin{align*}
\text{Water,} & \quad 784 \\
\text{Albumen,} & \quad 70 \\
\text{Fibrin,} & \quad 2.2 \\
\text{Red corpuscles,} & \quad 123.5 \\
\text{Globulin,} & \quad 7.5 \\
\text{Hematin,} & \\
\text{Cholesterine,} & \quad 0.08 \\
\text{Cerebrine,} & \quad 0.4 \\
\text{Serolene,} & \quad 0.02 \\
\text{Fatty matters,} & \quad 1.3 \\
\text{Oleic and margaric acids,} & \\
\text{Volatile and odorous fatty acid,} & \\
\text{Fat containing phosphorus,} & \\
\text{Chloride of sodium,} & \quad 3.6 \\
\text{Chloride of potassium,} & \quad 0.36 \\
\text{Trisacophosphate of soda,} & \quad 0.2 \\
\text{Inorganic salts,} & \quad 0.84 \\
\text{Carbonate of soda,} & \quad 0.28 \\
\text{Sulphate of soda,} & \quad 0.25 \\
\text{Phosphate of lime and magnesia,} & \quad 0.5 \\
\text{Oxide and phosphate of iron,} & \\
\text{Extractive matter, with salivary matter, urea, biliary colouring matter, gases, and accidental substances,} & \quad 5.47
\end{align*}
\]

\[1000:00\]
These several constituents are subject to some variations consistent with health. Thus the water varies in quantity according to the period since food has been eaten, the amount of bodily exercise, the state of the atmosphere, and all other events that affect the ingestion or the excretion of fluids. According to these conditions, it may vary from 700 to 800 parts in 1000. On the whole, however, a degree of uniformity is maintained, because nearly all those things which tend to lower the proportion of water in the blood, such as active exercise, or the addition of saline and other solid matter, excite thirst; while, on the other hand, the addition of an excess of water to the blood is quickly followed by its more copious excretion in sweat and urine.

Dr. Zimmerman has shown that the quantity of water in the blood is increased during its abstraction from an artery or vein. In bleeding dogs he found that the last drawn portion contained 12 or 13 parts more of water in 1000 than that first drawn. This experiment goes to prove that the fluid of the tissues must be rapidly absorbed during the operation.

The water in the economy is required for many important purposes. (1.) The proper viscosity of the blood, and the degree of its adhesion to the blood-vessels, is due to the presence of water in proper proportion. (2.) It determines to a great extent the volume of the blood. (3.) Water is the general solvent of the other materials of the liquor sanguinis. (4.) The activity of absorption by the blood-vessels depends upon the due fluidity of the materials to be absorbed, for it is well known that no fluids quickly penetrate the vessels but such as are of lesser density than the blood.

If the presence of water in excess continues beyond a short period, it is a certain symptom that the other constituents are defective in quantity, and that the condition termed anæmia is present.

Deficiency of water in the blood is witnessed in super-purgation, diarrhœa, &c. The deficiency, however, is generally of a temporary character, for nature prompts the animal to overcome it by drinking freely. The water also becomes deficient when an animal sweats profusely from any cause, and when prevented from allaying his thirst for a considerable period, as when hunting or going long journeys. A great mistake is made
by those in charge of horses who have a belief that it is a bad thing to allow a horse to drink while out on a journey or in the hunting-field. Small and repeated drinks are always beneficial, and prevent much suffering.

The albumen of the blood may vary, consistently with health, from 60 to 70 parts in 1000. Its amount, according to Andral and Gavarret, is notably increased in various diseases; but this excess does not appear to be characteristic of any. In acute rheumatism an increase was found varying from 4 to 24; in pneumonia the highest increase was about 12; in pleurisy the extraordinary amount of 34 in excess was once observed; and several other instances are mentioned of a lower degree. Excess of albumen in the blood is witnessed in the horse in a disease which the late Mr. Haycock termed hysteria.—(See Azoturia or Uraemic Paralysis.) Very probably the albumen in this disease is not only excessive in quantity but deteriorated in quality.

The albumen is defective in cases of albuminuria, in the "rot" in sheep, and in dropsies, whether dependent on organic disease of the heart, or on the presence of entozoa—distomata—in the liver. It is a remarkable fact, recorded by Andral, Gavarret, and Delafond, that in sheep affected with anaemia, with deficiency of the red globules, but without dropsy or entozoa, there was no deficiency in the albumen. Dr. Williams concludes from this, that cachexia and anaemia attended by dropsy owe this concomitant to a want of albumen in the blood; and he seems to be of opinion that a deficiency of the albumen, by destroying the spissitude of the blood, and allowing it to transude through the coats of the vessels, is a chief feature in the dropsical diathesis.

The fibrin of the blood.—When fresh drawn blood is left to itself, it very soon coagulates or becomes solid, and the substance thus becoming spontaneously solid is the fibrin, which, when separated from the blood, is a tough, elastic, tolerably firm, whitish-grey looking material, insoluble in water. Under the microscope the fibrin appears as a homogeneo-granular matter, with a more or less marked tendency to fibrillate. The white globules are usually seen imbedded in the mass, but they do not appear to modify the character of healthy fibrin. Fibrin, unlike the albumen and other constituents of the blood, does not appear to be derived directly from the food, but is elaborated in the tissue cells of the body from the bioplasma furnished by
the albumen. We may thus regard it as a formed and not a 
formative material; a substance, in fact, which has retrogressed 
at least a step in its vital importance. Although the fibrin is a 
product of the transformation of plasma, and as such is incapable 
of any but retrogressive changes, it is essential to the well-
being of the animal that it be present in the blood in quantity 
of about 3 parts in 1000.

MM. Andral and Gavarret record that, in the domestic animals, 
the fibrin diminishes before but increases after parturition. In 
the human female, however, it seems that the fibrin is decreased 
during the first six months of pregnancy—the average being 2.3; 
whilst in the last three months it is so increased as to average 4. 
Fibrin is rather more abundant in arterial than in venous blood; 
and it is mentioned by Schmidt that the blood of the portal vein 
contains only one-third of the ordinary amount of fibrin found 
in the blood of the jugular vein.

An excess of the fibrin—hyperplasma or hyperinosis—exists 
in all true inflammations. In acute rheumatism it is generally 
very high; in some cases, according to MM. Andral and 
Gavarret, as high as 12 parts in the 1000. In some exhausting 
diseases, and even in anemia, the fibrin is found occasionally 
increased in quantity. In rapid emaciation, more especially 
when accompanied by total loss of appetite, the quantity of 
fibrin is very materially increased. This is explained by 
the fact that fibrin results from the metamorphosis of the 
albumen of the blood and of the tissues. An increase of fibrin 
is found in meagre, half-starved horses, amounting to 7 or 8 
above the healthy mean. In one case, where no food was given 
for four days, it was found increased from 5 to 9. As the fibrin is 
increased by all inflammatory diseases, such increase can also be 
artificially induced by the application of external irritants, such 
as blisters, setons, or the actual or potential cauteries. This fact 
is of great importance therapeutically, and it should be borne in 
mind that the application of the so-called counter-irritants in 
extensive inflammatory diseases, tends to increase a condition of 
the blood which is already present to an abnormal extent.

Another very important circumstance connected with the 
increase of fibrin in the blood is pointed out by Andral, namely, 
that the effect of bleeding was not to diminish it. In M. Andral's 
experiments the red globules became diminished in number by
each abstraction of blood, whilst the fibrin often rose, sometimes considerably. The following examples are very conclusive:

MM. Andral and Cavarret found that the fibrin was increased in tubercular disease. In the crude state of the tubercles, the mean is about 4, when softening has commenced it is about 4·5, and when cavities have formed it is from 5 to 5·5, the red globules decreasing from the first.

Deficiency of fibrin—hypoplasma, hypnosis, or defective coagulating power—is observed in various morbid states, in disease, and in conditions bordering upon it, and is indicated by imperfect coagulation of the blood when drawn. It is deficient in all conditions where the blood is imperfectly arterialized; and this is in accordance with the physiological law that arterial blood is more fibrinous than venous. Thus, in death from asphyxia, the blood often remains semi-fluid, of a dark, tarry appearance, and coagulates only after being exposed to the air and absorbing oxygen. Various poisons seem to have the power of preventing the coagulation of the blood. Among these are hydrocyanic acid, carbonic acid, sulphuretted and carburetted hydrogen, and ammonia. Andral states that if a concentrated solution of carbonate of soda be injected into a vein, the animal presents the symptoms of blood disease, and that the blood is found fluid in the vessels. The same result may be produced by arsenious acid, digitalis, and oxalic acid. Other substances, although analogous to the carbonate of soda, seem to have no effect. Thus, the nitrate of potash does not always impede the coagulation of the blood; and Dr. Handfield Jones states that he has observed that liquor potassae, although given for several days, and until the animal's health was interfered with, did not at all interfere with the coagulation of its blood; and he infers from these observations that it is not the alkalies, as such, nor the neutral salts, as such, which produce the effects usually ascribed to them upon the blood, but certain substances of
particular qualitiea. In low fevers, influenzas of a typhoid character, particularly when animals so affected are stabled in ill-ventilated houses, the blood becomes remarkably fluid, and gravitates, even in cases that recover, to the depending parts of the body. Thus we find that in the so-called purpura hæmorrhagica the extremities and inferior portions of the abdomen, breast, and face become the seats of extensive swellings, caused by an accumulation of a preternaturally fluid blood in the vessels, and even in the tissues, whilst the appearance of petechiae, viceses, and the occurrence of hæmorrhages are due to the same cause. The partial suffocation to which animals are sometimes exposed when confined in buildings accidentally or otherwise burnt, produce a remarkable degree of fluidity in the blood. I have often witnessed this in horses and cattle which had been early removed from burning buildings,—in fact, when they had not been exposed to any fire, but to the effects of the smoke of smouldering straw, wood, &c. At the time, the symptoms of distress have not always been noticeable, and little has been thought of the matter. In the course of time, varying from a few hours to three days, the animals have presented symptoms of great respiratory disturbance, with hæmorrhage from the vessels of the lungs, the blood presenting a dark olive appearance, and coagulating but very imperfectly, even when exposed to the influence of the air. In such cases, it is quite fair to presume that the coagulating powers of the blood have been destroyed by the action of the products of combustion contained in the smoke, and that it—the blood—gradually accumulates in the vessels of the lungs until they have become congested, even to rupture of their walls. In apoplexy of the spleen and in "quarter-ill," the same hypnotic condition of the blood is seen, and is probably the cause of the congestions and extravasations which characterise those diseases. Although it may justifiably be said that imperfect coagulation, as well as the abnormal fluidity of the blood, depends upon the absence of fibrin, modern research has proved that fibrin, as such, does not exist in the blood, but is formed by the combination of two substances—or two modifications of the same substance—namely, globulin and fibrinogen; the former of which existing in the serum of the blood, and in some tissues of the body; whilst the latter, so

\[1 \text{ Fibrino-plastic.—(Schmorl.)}\]
far as it is known at present, exists only in the plasma of the blood, of the lymph, and of the chyle, and in fluids derived from them.

"Coagulation of the blood" (says Professor Huxley) "is an altogether physico-chemical process, dependent upon the properties of certain of the constituents of the plasma, apart from the vitality of that fluid. This is proved by the fact that if blood-plasma be prevented from coagulating by cold and greatly diluted, a current of carbonic acid passed through it will throw down a white powdery substance. If the white substance be dissolved in a weak solution of common salt, or in an extremely weak solution of potash or soda, it after a while coagulates, and yields a clot of pure fibrin. It would be absurd to suppose that a substance which has been precipitated from its solution, and re-dissolved, still remains alive.

"There are reasons for believing that this white substance consists of two constituents of very similar composition, which exist separately in living blood, and the union of which is the cause of the act of coagulation. These reasons may be briefly stated thus:—The pericardium and other serous cavities in the body contain a clear fluid, which has exuded from the blood-vessels, and contains the elements of the blood without the blood corpuscles. This fluid sometimes coagulates spontaneously, as the blood-plasma would do, but very often shows no disposition to spontaneous coagulation. When this is the case, it may nevertheless be made to coagulate, and yield a true fibrinous clot, by adding to it a little serum of blood.

"Now, if serum of blood be largely diluted with water, and a current of carbonic acid gas passed through it, a white powdery substance will be thrown down; this, re-dissolved in a dilute saline, or extremely dilute alkaline solution, will, when added to the pericardial fluid, produce even as good a clot as that obtained with the original serum.

"This white substance is called globulin. It exists not only in serum, but also in smaller quantities in connective tissue, in the cornea, in the humours of the eye, and in some other fluids of the body.

"It possesses the same general chemical properties as the albuminous substance which enters so largely into the red corpuscles, and hence at present bears the same name. But
when treated with chemical re-agents, even with such as do not produce any appreciable effect on its chemical composition, it very speedily loses its peculiar power of causing serous fluids to coagulate. For instance, this power is destroyed by an excess of alkali, or by the presence of acids.

"Hence, though there is great reason to believe that the fibrino-plastic globulin (as it has been called) which exists in serum does really come from the red corpuscles, the globulin, which is obtained in large quantities from these bodies by the use of powerful re-agents, has no coagulating effect at all on pericardial or other serous fluids.

"Though globulin is so susceptible of change when in solution, it may be dried at a low temperature, and kept in the form of powder for many months without losing its coagulating power.

"Thus globulin, added, under proper conditions, to serous effusion, is a coagulator of that effusion, giving rise to the development of fibrin in it.

"It does so by its interaction with a substance contained in the serous effusion, which can be extracted by itself, and then plays just the same part towards a solution of globulin, as globulin does towards its solution. This substance has been called fibrinogen. It is exceedingly like globulin, and may be thrown down from serous exudations by carbonic acid, just as globulin may be precipitated from the serum of the blood. When re-dissolved in an alkaline solution, and added to any fluid containing globulin, it acts as a coagulator of that fluid, and gives rise to the development of a clot of fibrin in it. In accordance with what has been just stated, serum of blood which has completely coagulated may be kept in one vessel, and pericardial fluid in another, for an indefinite period, if spontaneous decomposition be prevented, without the coagulation of either; but let them be mixed, and coagulation sets in.

"Thus it seems to be clear that the coagulation of the blood and the formation of fibrin are caused primarily by the interaction of two substances (or two modifications of the same substance), globulin and fibrinogen, the former of which exists in the serum of blood and in some tissues of the body, while the latter is known at present only in the plasma of the blood, of the lymph, and of the chyle, and in fluids derived from them."

Coagulation of the blood varies in different animals, and is
modified by disease. The blood of the horse, for example, coagulates more slowly than the blood of other animals and of man; hence what is termed the buffy coat is observable in coagulated healthy horse's blood, the buffy appearance on the top of the clot being ascribable generally to the fact that slow coagulation gives time to the blood globules, which are of higher specific gravity than the liquor sanguinis, to sink towards the bottom of the vessel before being incarcerated in the meshes of the coagulating fibrin. To prove this, fill two vials with the blood of a healthy horse, and to the blood in one add a small quantity of the chlorate of potash, and leave the other to coagulate naturally. In the course of a very short time the blood to which the chlorate has been added will be found firmly coagulated, and with but a slight or without any buffy coat; whilst the blood to which no addition has been made remains fluid for a much longer time, the globules falling to the lower parts, leaving the upper portion of the clot a straw colour.

During the first stage of coagulation, which is termed that of gelatinisation, the clot appears as a semi-solid mass. In the course of some time, however, it divides into serum and clot (crassamentum), the serum being pressed out by the fibrin. This shows that the fibrin possesses the power of contraction; and to the presence or absence of this power the further changes in the clot are due. The clot may be defective in solidity—gelatinous—or it may present an excess not only of fibrin, but of contracting properties. The shrunk, contracted, or cupped appearance of the clot indicates increased contractility and asthenic state of the system generally; whereas the gelatinous clot is indicative of an aplastic condition of the blood and an asthenic state of the system.
CHAPTER IX
PATHOLOGY—continued.

CHANGES IN THE BLOOD—continued.

ANEMIA, HYPHENIA, OR OLGÆMIA.

These terms are applied to that condition of the system in which there is a deficiency and poverty of the blood, a state brought about by loss of blood (hemorrhage), profuse discharges of any of the natural fluids of the body, as those of diarrhea or diabetes, in which it seems as if the blood globules were melted down to supply the profuse discharge; insufficient food, deprivation of fresh air, exhausting diseases, and the action of some deleterious agents, as witnessed in horses kept in ill-ventilated stables, or suffering from the influence of the glanders poison.

The symptoms of anemia are paleness of the visible mucous membranes, with often an unhealthy or slate-coloured appearance of that of the nasal cavity. In some instances a coppery appearance is witnessed; this is undoubtedly due to an altered condition of the globules, and a disordered state of the powers by which they are formed; the conjunctiva is pale, the mouth cool, and the tongue generally unnaturally soft. Young, growing animals, insufficiently fed and improperly cared for, exposed to the vicissitudes of the weather during the winter months, are reduced to an anæmic condition, manifested by emaciation, debility, and often a depraved appetite. When thus reduced, great care is to be taken that such are not suddenly turned into rich pastures, for it seems that the process of the formation and elaboration of the blood, and the organs concerned in it, are in such a state of disorder from long disuse, that the alimentary matters contained in luxuriant grass or nourishing food are transformed into an imperfect blood-plasma,—that is to
Changes in the Blood.

say, into blood abundant in quantity, but defective in quality, plasticity, and consistence, incapable of nourishing the tissues, and which ultimately becomes of itself diseased. From this cause—namely, the unwise and indiscriminate method in which young, rapidly growing, and imperfectly fed cattle are turned into rich pasturage in the spring, or put upon cake in the winter—such blood diseases as quarter-ill and splenic apoplexy are caused, and the life of valuable stock destroyed. In horses I have repeatedly witnessed the anaemic condition associated with such extreme debility of the muscular system as to simulate spinal paralysis, and in some cases paralysis, from the pressure of serous fluid on the spinal cord, has been actually present; but in the horse, as in horned cattle, active signs of disease are not manifested until there has been a sudden change to a nourishing diet. Sheep fed on food containing an excess of moisture, and during long-continued wet weather, become anaemic and dropsical. During the winter of 1872-3 this condition was exceedingly prevalent owing to the inferiority of the grasses, the moist condition of the turnips, and the humidity of the atmosphere; for in many instances no organic disease or parasitic invasion were present.

The anaemic condition is announced by abnormal sounds in various parts of the vascular system. These are called venous murmurs, and are ascribed to the thin, watery blood running with great rapidity in the ill-filled vessels, and are heard at the breast, at the base of the jugulars more particularly, and are, according to Dr. Williams, of the nature of ripples, "the natural inequalities of the surface over which the current of blood passes being sufficient to occasion, in its dilute and diminished condition, vibrations and sonorous gushes, which would not occur in a fluid of greater density.

The nutrition of the various structures of the body being dependent upon a healthy condition of the circulating fluid, it naturally follows that wasting, emaciation, and debility are the results of anaemia. In none of the anaemic states, unless it be intensified by an excessive discharge, as in diarrhoea, is rapid emaciation so prominent a symptom as in that caused by the presence of the glanders poison.

The pulse in anaemia is feeble, thready, often jerky and irregular, and any sudden excitement produces a degree of palpitation of the heart, leading one to suppose that the organ is
hypertrophied, so loud, sharp, and knocking is the character of its contraction.

The contractile power of the muscles is generally much impaired, fatigue being soon induced; the bowels are often constipated, the constipation being due to a want of tone in the muscular coat.

Though the muscular system manifests great loss of power and tone, the nervous system seems to be exalted, excitement being induced by very trivial causes, but this seeming exaltation is in reality due to loss of strength and power. "The nervous system in the anaemic condition may be likened to a spring which originally was of a certain strength, requiring a certain impressing, and reacting with a corresponding force, but having become much weakened, is bent by much less force, and reacts also with much less. Mobility and debility may be said briefly to be the chief characteristics of the nervous actions in the anaemic."—(Dr. HANDFIELD JONES.)

The digestive powers are feeble and imperfect, and colicky pains are induced by trivial causes; tympanitis is frequent, and results from the defective power of the muscular coat of the alimentary canal. The secretion of the gastric juice is also impaired, and results from the gastric follicles being insufficiently supplied with nutritive materials. This constitutes a further cause for the continuance and aggravation of the anaemic condition, and acts as a bar to healthy digestion, though the food supply be liberal and good, for healthy chyle cannot be formed to renovate the blood if the primary digestion be impaired. Most probably the accession of disease, when nutritious food is supplied to half-starved animals, is due more particularly to this cause.

Anaemic swellings of the limbs is a common symptom of anaemia in the horse, but is rarely witnessed in horned cattle. In sheep, as already stated, dropsy of the cavities is frequently witnessed. Under the term "spontaneous anaesara," Mr. Brown of Melton-Mowbray has described the anaemic condition, with dropsy of the cavities, in the horse. Mr. Brown says the disease attacks one and two year old colts, grazing during the winter season in wet, poor moorland, and is very prevalent in Lincolnshire; the disorder being manifested by swelling of the legs, sheath, belly, and lips, and finally the eyelids, the breath and
excretions exhaling a peculiar odour. The animal turns sluggish and depressed, loathes its food, and seldom lies down; the respiration becoming accelerated and the pulse feeble. Loss of flesh, prostration of strength, short and difficult respiration, frequent and indistinct pulse, and finally diarrhoea, which, if once established, carries off the animal in despite of all remedies. The post mortem examination reveals yellowness and flaccidity of the muscular system, effusion into the areolar tissue, thickening of the pericardium and pleura, with effusion into their cavities, often so great as almost to cause collapse of the lungs and arrest of the heart's action; effusion into the omentum, mesentery, and peritoneum.—(See Veterinarian, 1832.)

The causes of anaemia being generally apparent, I need scarcely state that they must be removed, as a primary step in its successful treatment; and for this purpose, it was, or is, the custom in Lincolnshire, to take up young colts for the month of August, and feed them during that time exclusively on dry provender. When anaemia is due to the operation of a specific virus, as that of glands, or when at any time its cause cannot be discovered, the employment of any mere remedial measures is of very doubtful utility. Again, the anaemic condition, which can be ascribed to well-known and preventible causes, may have existed so long, or operated so strongly on a constitution perhaps naturally weak, as to act as a determining cause of some cachectic condition such as tuberculosis, or to disease of the osseous system; or may have so impaired the action of the heart—the fibres of which have become organically altered, degenerated—as to prove fatal, notwithstanding all rational treatment. The treatment calculated to overcome anaemia consists in allowing nutritious diet, carefully selected, and of easy digestion: for horses—oats, beans, crushed linseed, the latter in small quantities, and good hay; for cattle and sheep—an allowance of oilcake in addition to their ordinary fodder, which should be of good quality, and sufficient but not over-abundant in quantity; in addition to which the salts of iron are to be given in small and repeated doses. If the digestion be weak and the appetite bad, the iron is to be withheld, the vegetable tonics and the mineral acids given. Should the appetite be depraved, or if there be an unnaturally acid condition of the juices of the stomach, manifested by a tendency on the part of the animal to lick the walls and grind its teeth, with sourness of the mouth and fætor of the fæces, the alkalies are to be com-
bined with the vegetable bitters. For the constipation, which is due to debility of the muscular walls, nux vomica is very useful, mashes being now and then allowed. To the food above prescribed, it may be necessary in aggravated cases to allow the animal to have a quantity of milk twice a day—say one gallon of skimmed milk night and morning, mixed with oatmeal or porridge; this it will usually become very fond of in a day or two. The system of forcing food, by horning it, upon animals is not to be recommended; for what an animal does not eat spontaneously is not digested, but disorders the digestive system, and destroys any little appetite that may possibly remain.

Horses, during the spring and autumn, when casting their coats, suffer more or less from anemia and debility, and are incapable of performing the same amount of work as at other seasons of the year. A little rest and gentle treatment at this period often prevent the accession of disease. Again, horses whose coats are very long, if kept in stables of even ordinary warmth, suffer from anemia, with anasarca, and even dropsy of the serous cavities, which will increase notwithstanding the most powerful tonics and the most nutritious food, until their heavy coats are removed by clipping. I have seen the lives of many valuable horses saved by timely clipping.

In all anemic cases the secretory organs—the kidneys, skin, &c.—are very apt to become torpid; the urine is scantily secreted, the skin dry and harsh, the animal hide-bound, as it is termed. These complications must not be overlooked, or the blood will become loaded with effete materials. To stimulate the kidneys the spirits of nitrous ether may be given occasionally, and to excite the skin nothing is to be compared to good grooming, particularly damp wisping the whole surface of the body. Warmth, comfort, gentle exercise, and pure air all play an important part in the treatment, and should by no means be neglected.

The changes and alterations in the several constituents of the anemic blood are briefly as follows:—(1. The red corpuscles are remarkably diminished; they have been known in the human being to sink as low as 27; they also appear to contain less haematin, and are somewhat paler than those of healthy blood. (2.) The amount of white corpuscles does not appear to be altered, (3.) The fibrin, or the constituents by the interaction of which the fibrin is formed, is never found below the normal standard.
in some cases its quantity is notably increased, particularly if inflammation of any organ is present. (4.) The solids of the serum are not found much altered. (5.) The quantity of water is more or less increased in proportion to the diminution of the globules.

LEUKAEMIA OR LEUCOCYTHEMIA

Is a condition of the blood characterised by a large increase in the number of the white corpuscles, associated with a new formation of lymphatic tissue (lymphadenoma) in the lymphatic glands, spleen, and other organs; but the association of leukæmia with lymphadenoma is not constant.

An increase of white corpuscles is also witnessed in some cases of fever and glanders; but the true nature of leukæmia seems to depend more upon an inability in the white and lymph corpuscles to form red blood globules, than upon any actual growth of lymphatic tissue.

PLETHORA.

The possibility of there being at any time an increased quantity of blood in the animal body—plethora—is denied by some observers. The condition, however, is recognised by veterinarians as one of not infrequent occurrence, more especially in young fast-thriving animals, when fed upon very highly nutritious food. The occurrence of a general plethoric condition is also recognised by Sir Thomas Watson, who says—"Perhaps it may not be so obvious that the whole quantity of blood throughout the body is sometimes in excess. . . . . .

Fall living and a sedentary life are causes likely to occasion general plethora, and they do occasion it. The full diet, so long as the digestive powers are perfect, provides more chyle, conducts into the blood a larger quantity of its proper and... . . . . Their entire vascular system is preternaturally distended. If you open a vein you find that they [persons in a plethoric condition] bear a copious abstraction of blood without fainting, and are even refreshed by it; and the blood drawn separates into a large and firm mass of coagulum, with but little serum. Keeping to the nomenclature we have already employed, we might say that there is here hypertrophy of the blood."

The treatment of these cases is sufficiently obvious—abstraction of blood, purgatives, a restricted diet, and increased exercise.
CHAPTER X.

PATHOLOGY—(continued).

CHANGES IN THE BLOOD—(continued).

DEFECTIVE EXCRETION.

Sir Thomas Watson, in his graphic language, says that "the animal fluids are—the blood, the fluids that enter the blood, and the fluids that proceed from the blood.

"The fluids that enter the blood are of two kinds—

"1. Those by which it is renewed and enriched.

"2. Those which enter it in order that they may be conveyed out of the body."

A defective condition of the fluids which enter the blood to renew and enrich it—namely, the chyle—produces the condition already described—anaemia. A modified or altered condition of the chyle—that is to say, chyle imperfectly developed, containing abnormal constituents, products of imperfect digestion or elaboration, or directly derived from the ingesta—is a frequent source of alteration in the blood and of disease.

The fluids which enter the blood for the purpose of being conveyed out of it are the products of the metamorphosis of the chyle and tissue, accidental materials contained in the food, products of imperfect digestion, superabundant nutritive elements unappropriated by the tissue cells, and undergoing degradation within the blood-vessels, or in organs such as the liver. For the removal of these effete materials the organs of excretion are provided. When the organs of excretion are disordered or diseased, it follows that such products accumulate in the blood, contaminate and render it unfit for the proper nourishment of the body.
CHANGES IN THE BLOOD.

The most remarkable and perhaps the most important change in the blood from defective excretion is that produced by arrested or deficient secretion of urine. In some experiments performed by M.M. Prevost and Dumas, who removed the kidneys of dogs and cats, on the third day after the operation vomiting came on, with diarrhea of a copious brown liquid containing ammonia, from transformation of the urea, eliminated from the intestinal mucous membrane; fever, with heat sometimes as high as 110°, sometimes as low as 92°; small and very frequent pulse, laboured breathing, and death, from the fifth to the ninth day.

The post mortem appearances were, effusion of serum in the brain, much mucus in the bronchial tubes, bilious fluid and feces in the intestines, an appearance of inflammation of the liver, great contraction of the urinary bladder, the blood more watery than usual, and containing urea; five ounces of blood of a dog yielding twenty grains of urea, and two ounces of cat's blood ten grains.

Defective secretion of urine, resulting from disease of the kidneys, induces symptoms very similar to the above, differing in degree and intensity according to the extent of the kidney disease. Thus, in acute nephritis, or in rapid degeneration of the kidneys, such an amount of urea and other effete urinary matters may collect in the blood as to cause convulsions, delirium, suffocative discharge of mucus from the bronchi, diarrhea, and serous effusion into the cavities and areolar tissue. In subacute cases dropsy gradually ensues, the animal finally becoming cachetic. All these effects may be traced to excrementitious materials retained in the blood, especially urea, which if in great amount acts as a narcotic poison, in smaller, as an irritant, inducing inflammations in various membranes; in the horse, more especially in the membranes of the spinal cord, and the neurilemma of the great nerves given off from the lumbo-sacral plexus.

TRANSFORMATION OF CHYLE AND OF THE TISSUES.

The blood is kept in its normal or healthy condition by being supplied with new elements derivable from the chyle, and by having the products of the metamorphosis of the tissue and all
its effete constituents removed by the various secretory organs. When any of these conditions are absent, or when, as sometimes happens, the waste of tissue is so rapid as to preclude the elimination of all its products, a mal-condition of the blood-mass is induced, which may lead to grave local complications and diseases of important organs.

Some chemists hold the opinion that urea more especially is derivable from waste of tissue only, and not from any change or metamorphosis in the chyle or blood. I shall, however, endeavour to prove that an uremic condition of the blood may be caused by chyle imperfect in quality or excessive in quantity; the imperfection of the quality being the result of disordered digestion, or of the ingestion of food unfitted for healthy chylification; and excessive in quantity from the animal being fed upon aliment too rich for its requirements. In order to understand this, however, the student must be made still further acquainted with the process of nutrition, and this may be divided into—(1.) The introduction into the stomach and alimentary canal of the food to be digested: (2.) The formation of the chyle and blood, and the changes which the latter undergoes in the lungs: (3.) The passage of nutritive plasma from the blood to be transformed into tissues: (4.) The metamorphosis and re-absorption of the tissues: (5.) The excretion of these effete materials from the body by the various excretory organs.

I shall, however, confine myself, very briefly, first, to the digestion of the food, and the formation of the chyle; and second, to the changes and transformation of the chyle and blood in the vessels.

All kinds of food are resolvable into carbon, hydrogen, oxygen, nitrogen, and mineral constituents; and food to maintain the animal body in a state of health must contain all these various substances in due and proper proportions, and in quantities depending upon its necessities and wants under the circumstances in which it is placed, the amount of work it is compelled to perform, the amount of air it breathes, and upon various peculiarities affecting its powers of digestion, whether the animal be carnivorous, omnivorous, or herbivorous.

It is immaterial to what natural order the animal may belong, the proximate chemical principles required for its nourishment are the nitrogenous—albuminous, non-nitrogenous—starch, gum,
sugar, oil, and the mineral salts, more particularly the phosphate of lime and the chloride of sodium, with iron, potash, &c.; and it has been proved that all nutritive food must contain the three principles, and that the absence of any one of them induces starvation and death. It is also proved that the chemical constitution of plants and animals is nearly identical, and hence food derived from plants contains the substances of which the animal body is made, and by which it is nourished. Some animals are carnivorous, and must be maintained on flesh. In others life is supported by plants and grain. The digestive organs differ somewhat in these; but the digestion—that is to say, the ultimate end of the digestive process—is the same in all, namely, the formation of a whitish emulsion, the chyle, which is absorbed from the intestinal canal, and conveyed into the general circulation, thence to be transmitted to all parts of the body, giving to each materials which it may at the time stand in need of for its development, growth, and vitality. In all animals water is also necessary, not only as a diluent, but as forming a component part of the blood and tissues.

It must be understood that mere nitrogeous, non-nitrogeneus, and saline materials of food will not serve the purposes of healthy nutrition; they must be blended and united to form the kind of food natural to each class of animal, and capable of being finally converted into albumen, fat, and salts, as all these exist in every tissue; the fibrous and muscular organs containing much albumen, the glands and areolar tissue fat, and the bones mineral matters.

The quantity of food required is greatly influenced by the weather. If cold and condensed, the air contains more oxygen, which, rapidly meeting with the tissues for the purpose of maintaining the normal standard of animal heat, the body demands more nourishment to prevent emaciation. Again, work or severe bodily exercise causes waste of tissue, and at the same time, if not too severe, stimulates the appetite, and improves the powers of digestion. The demand for more food, the increased appetite, and the exalted digestive powers being necessary to the wellbeing of the animal, as compensating agents, by which more food is partaken of and digested, in order to make up the waste of tissue induced by the bodily exercise, a more or less even balance is thus kept up between the secondary digestion,
or destructive process, and the primary digestion, or compensating process.

It is very true that a healthy animal will retain its appetite and be capable of partaking of food and digesting it for a considerable time without exercise, and, under certain circumstances, which sometimes seem inexplicable, remain in health. Generally, however, the excessive amount of nutriment is stored up amongst the fatty tissues in various organs; and the storage of fat may so far be looked upon as an act of excretion, bearing out the proposition of Treviranus, that "each single part of the body, in respect to its nutrition, stands to the whole body in the relation of an excreted substance;" or, in other words, every part and tissue of the body, by taking from the blood the peculiar substance of which it is made, or which it can accommodate and store for future use, acts as an excretory organ, inasmuch as it removes from the blood that which, if retained, would be injurious to the rest of the body.

In many cases, however, this act of accommodation, as it may be termed, is insufficient; and in animals fed upon rich food, particularly nitrogenous food, the blood-mass becomes so impure, from the presence of effete materials, that the whole body is poisoned. For example—and this not at all uncommon—a horse is kept in the stable for some days, perhaps three or four days, and fed upon its usual liberal allowance of food, consisting of hay, corn, and water. When put to its work it usually commences its labour with the greatest spirit and animation, every nerve and muscle being, as it were, in the highest state of functional perfection; but before it has proceeded more than a few miles on the journey, very often before it has gone a mile, it suddenly staggers and falls paralysed. Sometimes it may be able to rise and walk slowly to its stable; sometimes it never rises again. Shortly after the attack it is observed to pass large quantities of a dark coffee-coloured urine, so dark, indeed, as to lead many observers to suppose that it is blood. Careful observations have, however, enabled me to determine that such urine contains no blood, and little or no albumen, but that the darkness of its colour depends upon an excessive quantity of urea, and probably creatine and creatinine, products of the degradation of the nutrient materials which had accumulated in the blood-mass during the period the animal was at rest.
It has been maintained by some writers that urea is a product formed in the kidneys, and by others that it is an oxidized albuminous material, due to the degradation of muscular tissue, brought about by muscular exertion only, and merely excreted by the kidneys.

Without a doubt urea is an oxidized or degenerated condition of albumen, but the occurrence of the immense quantity of it in conditions of the animal body opposed to that of tissue change, I think, disposes of the idea that urea is due only to metamorphosis of tissue, and supports the theory that it is formed in the blood itself, or in the liver, as advocated by Meissner.

The rules for the proper treatment of disease depending on blood loaded with effete materials are—1st. To clear the intestinal canal of the materials with which it may be loaded, and from which additional matter may be absorbed and conveyed to the blood: 2d. To stimulate the powers of the excretory organs, kidneys, and skin: and 3d. To attend to the comfort of the patient, and particularly to supply it with abundance of water, which not only allays the thirst, but dilutes the blood and stimulates excretion.
CHAPTER XI.

PATHOLOGY—continued.

CHANGES IN THE BLOOD—continued.

HYPEREMIA OR CONGESTION.

The liability of the blood to be variously altered and modified having been described in the preceding chapter, it now becomes necessary to enter into a consideration of certain changes which may occur in its circulation, arising from an alteration in the condition and properties of the blood-vessels, and causing an interference with its natural flow.

By hyperemia is meant an excess of blood in the vessels of a part. It is of two kinds, namely, active or arterial, and mechanical or venous.

Active hyperemia is an excess of blood in the arteries, with, most commonly, an increased rapidity of the flow, and arises from increased blood pressure and from diminished arterial resistance.

Hyperemia from increased blood pressure occurs from interruption of the main current of blood in any particular part, owing to which increased pressure is thrown upon the collateral vessels, which thus become dilated, the amount of blood in them being increased, and its flow accelerated. This kind of congestion is seen after the main current of a part has been obstructed from any cause, and is known as collateral hyperemia.

Congestion of the vessels of one part from an obstruction to the flow of blood in another, is also well exemplified in congestion of the internal organs from contraction of the superficial capillaries, so often produced by exposure to cold.

In some instances, the introulsive operation of cold is so great that the internal capillaries become loaded with blood to such
an extent that their walls give way, and the blood is extravasated into the surrounding tissue. In this manner apoplexy of the lungs is brought about, and so great is the extravasation in some rare instances, that the blood has found its way into the bronchi and trachea, and has been finally expelled through the nostrils. The local constricting effect of cold is best witnessed upon the human body, more especially in persons of weak circulation, in whom, very often after washing or bathing in cold water, the fingers are quite bloodless, pale, and numb. If we reason upon this circumstance, and bring such reasoning to bear upon our own subject, can we wonder that exposure to external cold is followed by internal congestions.

In many cases, however, nature provides a guard to the influence of cold upon the skin, by furnishing animals with coats of hair or wool suitable for their several necessities, and it is only in animals which are casually exposed to such cold that we witness its effect in causing internal congestions.

Congestion from diminished resistance arises from atony of the wall of the vessels. This atony, loss of power, or relaxation of the vessels, is generally due to paralysis of their muscular walls, and most commonly occurs in vessels least provided with muscular fibres, that is, in the capillaries and veins of organs easily distended, and which are composed of much areolar tissue. This paralysis of the muscular walls may be due to an influence operating upon the vaso-motor nerves, or to irritation of a sensory nerve. Pressure upon the great sympathetic nerve in the neck causes active congestion of the head and neck, and most probably the congestion of the brain, redness of the conjunctiva, suffusion of tears, and other signs of fulness of the vessels of the facio-cranial region, with the coma and delirium which are sometimes associated with gastric or intestinal disease, are due to pressure upon the cardiac branches of the great sympathetic or ganglionic nerve. It is very true that some emotions are attended with hyperæmia; and it may be said that the meningeal or cerebral congestion of parturient apoplexy is due to some sympathetic influence which the stomach has upon the brain. The question need not be discussed here, as it will again come under consideration; and let it suffice us for the present to know that disorder of the stomach is capable of producing congestion of the brain.
In hemiplegia, a disease rarely witnessed in the horse, but to which horned cattle are liable, congestion of the vessels of the paralysed side is a prominent symptom.

Atony of the arterial walls may be due to degeneration of their muscular and internal coats. It is most commonly the cause of the various congestions seen in old animals.

Mechanical congestion occurs chiefly in the veins, and is produced by anything which interferes with the flow of the blood through them, such as obstruction of the vein leading from a part, arising from pressure upon its walls, or the pressure of a thrombus or clot within its canal. Thus congestion may be induced by the pressure of a tight bandage; and again, congestion of the portal vein is caused by cirrhosis or other disease of the liver, which causes pressure upon its venous branches. Disease of the valves of the heart produces fulness of both the pulmonary and systemic veins. When the incompetency is limited to the mitral valve, the congestion is mostly limited to the lungs, while insufficiency of the tricuspid causes congestion of the systemic veins. The character of congestion beginning in the veins is that the veins as well as the capillaries are distended, giving the part an arborescent appearance, which has a much more permanent character than congestion beginning at the arteries. Arterial congestion, especially that of an active type, very often disappears shortly after death by the post mortem contraction of the vessels.

In addition to mechanical obstruction to the flow of blood, there are various and important causes of venous congestions, such as diminished cardiac power, gravitation, an altered condition of the blood, and defective secretions.

1. Diminished cardiac power.—The contractile power of the heart becomes diminished in many diseases, and death may result, not so much from the original disease from which the animal has been suffering, as from congestion of some vital organ, more especially the lungs or the brain, arising from the inability of the heart to propel the blood through the vessels of such organ. The example most familiar to the veterinarian of this form of congestion is acute congestion of the lungs caused by over-exertion. Many instances of this occur in the hunting-field during severe runs; horses out of condition, and unfit for very prolonged and severe galloping, falling down and rapidly sinking
from this cause. This form of congestion becomes aggravated by the blood remaining unchanged, for it is found that when the blood is not properly changed in the lungs, its passage through them is partially impeded, that it accumulates in them, in the right side of the heart, and in the veins generally.

2. *Gravitation.*—The veins of the extremities and other depending parts of the body are congested from this cause. It indicates an atonic condition of the system generally, with diminished cardiac force; and is commonly associated with all the exhausting diseases of the horse, more especially if the animal is not exercised. Congestion from gravitation is also caused in many healthy horses by want of exercise. Indeed, a due amount of exercise, when in a condition to take it, seems to be of greater importance to the horse than to horned cattle. The cow or ox will remain in the stall for weeks, or even months, tied in one position and receiving no exercise, but the limbs never swell, and there are seldom any signs of venous congestions; not so with the great majority of horses. Now and then, however, a horse is met with whose limbs never swell from want of exercise, but as a rule horses when not exercised suffer from swellings of those depending parts of the body farthest removed from the centre of the circulation. Other horses habitually suffer from swelled legs, no matter how carefully and properly they are fed and worked. The debility produced by the process of “casting the coat” causes congestion of the vessels of the depending parts.

A very remarkable example of the effects of gravitation in producing congestion used to be frequently witnessed in the days when bleeding was so commonly performed, and when inflammation of the jugular vein was more frequently met with than now.

The loss of a jugular from the formation of a thrombus within it, and consequent obliteration of its canal, did not seem to interfere with the cervical circulation until the animal was turned out to grass; but immediately this was done, the animal’s head would commence to swell to a most alarming extent, proving that, although the collateral circulation was sufficient, so long as the horse was fed from the rack or manger, it was quite insufficient when the head was depressed whilst grazing.

3. *Altered conditions of the blood.*—Many congestive diseases,
more especially those of horned cattle and sheep, are caused by
an altered condition of the blood. How this determines a con-
gestion of an organ or a system of organs it is difficult to under-
stand; but such diseases as apoplexy of the spleen, quarter-ill,
and other anthracoid diseases manifested by extensive congestion
and extravasations, are all due primarily to blood alterations,
the lesions of organs being secondary to and depending upon
the blood disease. A thin watery state of the blood, as well as
the presence of some specific blood poisons, and the operation
of malicious influences, have also in many cases a tendency to
cause congestions of organs.

4. **Defective secretion**, either from an organ or a secretory sur-
face, is a cause of congestion of such an organ or surface; and it
is found that the means which increase the secretion will often
remove the congestion. It must, however, be borne in mind
that diminished secretion is usually the result of the congestion,
and that the means which have the power of exciting the secre-
tion of such a part very often, in virtue of their irritating effects
upon it, increase the congestion, or, what is perhaps of greater
moment, transform a mere congested condition into that of in-
flammation.

Many writers seem to confound congestion with inflammation,
and we continually see slight inflammations described as con-
gestions. It appears to me that a distinction should be made
between the two conditions, and that a congestion should be
defined to be a fulness of the vessels of a part or parts arising from
various causes, without the occurrence of any primary important
perversion of the nutrition of that part; and that inflammation
is a perverted condition of the nutritive function of a part,
accompanied in the majority of cases by a congested condition
of its vessels; such congestion, however, not being necessary to
the inflammatory process, for it is found that inflammation
involves the non-vascular as well as the vascular structures of
the animal body.

The results of mechanical congestion are transudation of
serum, hemorrhage, thrombosis, and gangrene; and of active
hyperemia, increased redness, elevation of temperature, and a
sense of throbbing, succeeded, if the congestion continues, by
enlargement of the small arteries and thickening of their walls;
function being in some cases exalted, more especially if the
CONGESTION BE IN A NERVOUS CENTRE, WHILST IN OTHER INSTANCES FUNCTION BECOMES DIMINISHED. Thus a long-continued congestion of a secretory organ arrests, or very considerably diminishes, the function of that organ.

The congestion or fulness of the vessels is somewhat relieved by transudation of serum into the tissues, or into cavities, constituting cedema, anasarca, and dropsical effusion. For this reason the limbs swell when their vessels are congested from debility or want of exercise; and the peritoneal cavity becomes filled with fluid, constituting ascites, when the portal veins are in any way obstructed. The transuded serum generally differs from that of the blood, in containing less of the solid blood constituents and more water; it has also a lower specific gravity. If exposed to the air it will sometimes coagulate, forming rather a gelatinous mass than a firm fibrinous clot.

When the obstruction is very great the serum partakes more of the nature of the blood plasma; and it is now ascertained that in some instances the blood globules may escape through the walls of the capillaries without rupture. This fact was discovered by Cohnheim, who, by applying a ligature to the femoral vein of the frog, observed, when the congestion of the vessels became very great, that the red corpuscles passed through the capillary walls, and in so doing assumed an hour-glass shape, or became constricted in their middle. This fact explains to some extent how, in some cases of purpura, transudation of blood takes place into the tissues without rupture of the vessels.

Congestion from obstruction producing gangrene is seen in strangulated hernia, and in invagination of a portion of the intestines. Gangrene from obstruction is always of the moist kind, whereas that from arterial incompetency is of the dry kind. In the one the blood supply is scarcely or not at all interfered with, but the return of that blood is arrested, stasis is produced, the blood thus imprisoned transudes into the tissues, and, rapidly dying and decomposing, adds to the rapidity of the death and decomposition of adjoining structures. In the other, or gangrene from want of blood, the part turns pale and dry, shrinks, becomes mummified, or crumbles into fragments.

The occurrence of thrombosis, or the formation of clots in the congested vessels, results from the blood coagulating within them during life, and may arise in congestion of any part, and
from any of the causes already enumerated. When caused by direct pressure, the coagulation commences at the point where the obstructing cause comes into contact with the vessel, and extends as far as the collateral branches; when from debility, diminished cardiac power, or gravitation, the coagulation commences first behind the flaps of the valves, and appears to be owing to the force of the current being insufficient to completely open the valves. The blood thus allowed to lodge and stagnate coagulates and forms a thrombus or clot, which may finally obstruct the whole venous channel as far as the next large collateral branch.

Treatment of congestion.—The most important means for the removal of congestion are those which tend to remove its cause; and if the causes already enumerated are borne in mind, the practitioner will at least have some guide to the proper line of treatment. When the congestion is due to the influence of cold upon the surface, clearly the first step is to restore the circulation of the skin by warmth, friction, and by the administration of remedies, such as the spirits of nitrous ether, which are known to promote diaphoresis. If the congestion be due to diminished cardiac power, or debility of the vessels—and this is often induced by want of exercise—the lost power and tone must be restored by good food, pure air, regular and moderate exercise, and tonics. If the debility of the vessels be very great and obstinate, the effects of ergotine may be tried. This remedy acts by producing contraction of the blood-vessels; it may be very conveniently used hypodermically. The effects of bandaging, in supporting the weakened vessels of congested limbs, should not be lost sight of, nor its application neglected. In many instances a watery condition of the blood is associated with debility of the circulatory apparatus: in such cases tonic remedies combined with diuretics act most favourably.

In severe internal congestions, where not only the organ chiefly affected is filled with blood, but the right side of the heart and the great veins also, the necessity of affording mechanical relief becomes a serious question, and very often an urgent necessity. It is very true that severe internal congestions, more especially those of the lungs and brain, are generally associated with greatly diminished cardiac power, feeble pulse, and nervous prostration; and if we were to admit what is so commonly in-
sisted upon, that the course of treatment is to be guided by the condition of the pulse, then the withdrawal of blood would be contra-indicated in every instance. But practitioners who have thought over the matter know full well that a moderate bleeding is followed by a diminished acceleration of the pulse, and improvement in its tone, and that many congestions are immediately relieved by such procedure. The explanation is not difficult. In cerebral congestions the diminished cardiac power and feebleness of the pulsations are caused by the pressure of the congested vessels upon the brain substance: in many instances this pressure is increased by the transudation of serum from such congested vessels. By diminishing the brain pressure by the abscission of blood, the cause of the debility is at once removed. The heart is now able to beat fully and strongly, and thus a small, feeble, or even thready pulse is changed into a full, soft pulsation. The variety of opinions held as to the possibility of causing an alteration of the fluids within the cranium by bleeding or otherwise, need not be discussed at present. My own experience leads me to the conclusion that a comatose condition produced by cerebral or cerebro-meningeal congestion is often removed, the pulse being at the same time improved in tone, by a moderate bleeding. Pulmonary congestion and the feebleness of the heart's action—the "oppressed action" as it has been termed—are aggravated by the right side of the heart and the great veins being choked with blood. In this instance, it is true, the withdrawal of blood does not relieve by removing the primary cause—that is, the congestion of the pulmonary capillaries—but, a most important complication, it diminishes the supply of blood to the already overloaded heart, and through it to the already congested vessels. Bearing this in mind, the rapidity with which the withdrawal of a large stream of blood produces an impression will be understood; indeed, it can most truly be stated that the relief afforded does not depend so much upon the quantity withdrawn, as upon the rapidity of the withdrawal. For example, six or eight quarts of blood might be abstracted in a small or trickling stream, and afford no relief, but, on the contrary, do much harm, by causing debility or exhaustion; but a smaller quantity, if withdrawn rapidly, may be followed by a marked remission of all the distressing symptoms. In the one case, the blood supply to
the heart within a given time has scarcely been interfered with, while, in the other, the quantity returned by the veins has been most sensibly diminished, time has been afforded to the congested vessels, become to some degree emptied, to regain their lost tone, and for the circulation generally to be restored to its equilibrium. In these congestions the administration of diffusible stimulants after the bleeding will still further restore the lost power of the propulsive force and of the debilitated walls of the vessels; and, in virtue of their exalting action, will diminish the internal congestion, by causing an increased circulation of the vessels of the skin and excretory organs.

LIPÆMIA, OR FATTY BLOOD.

In February 1882 I was consulted by a gentleman living in the West Highlands regarding a fatal disease which had appeared amongst his ewes, mostly among gimmers.

The history of the outbreak was very meagre, and was from the farm manager, who stated—

"The appearance when first attacked, or rather when we notice them, is that they do not follow the flock, and, when walking, propping their legs as appearing to keep them from falling, which they often do, always going down head first.

"Their droppings not at all natural, and mixed with a slimy mixture of blood. They live from three to four days after we detect them ill.

"Their food for the last three months, turnips carted out on grass land, with an allowance of half a pound of Indian corn and cotton cake mixed per day.

"I may add that they were turned into the turnip fields to pick up broken and small turnips, but were only there about three weeks, during which time they had full turnips, and looked the very picture of health.

"Mostly all the dead ewes when opened have shown a great deficiency of blood."

The proprietor in a short note informed me that "the only treatment that has been attempted is giving a dose of castor oil, and that some of those showing symptoms of disease improved since the giving of cotton cake was discontinued."
These letters were accompanied by the carcase of a sheep of the Shropshire Down breed in an advanced state of decomposition.

On a post mortem examination being made the whole body was found to be loaded with fat; that of the abdominal parietes being several inches in thickness; the sublumbar region had many pounds of fat in it, and here it was found that the interior of the fatty masses had undergone crystallisation; well-formed crystals of stearine and margarine being found in the midst of a dry kind of débris.

The structures of the liver and of the heart were not only thoroughly infiltrated with oil globules, but had undergone fatty degeneration to an advanced degree; the lungs were congested, and the large pulmonary vessels filled with thrombi; the cardiac ventricles were quite full of blood, showing that death had been induced by asthenia and pulmonary congestion.

Microscopically examined, the blood (which was pale in colour when seen with the naked eye) from the heart, pulmonary vessels, and from other parts, was found to be loaded with oil globules, as represented in the drawing, which was made on the spot.

It will be seen that the oil globules vary in size, some being smaller, some much larger than the red blood corpuscles. It was unfortunately, however, impossible to prepare microscopic slides.
of the blood and tissue owing to the advancing decomposition; but notwithstanding this, the fat gave the usual reactions with perosmic acid and other staining materials.

I am not aware that this disease has ever been observed by any veterinary writer, and it was only in 1874 that Professor Kussmaul first drew attention to it in the *Deutsches Archiv für Klinische*, as causing a remarkable mode of death in diabetes mellitus of the human being; the fatal symptoms consisting in a peculiar kind of dyspnoea, which after a time was accompanied by and ended in coma.

In 1879, the late Professor Sanders, and D. J. Hamilton, M.B., Edinburgh, investigated two cases after death from diabetes, and found a condition of the blood similar to that described above.

Death from lipæmia has also been observed in cats which have suffered from exhaustive diseases, accompanied by great emaciation, but no cases have hitherto been recorded in which this condition of the blood has accompanied obesity of the body generally.

Fatty embolism of the pulmonary artery is a cause of death in some cases of compound fracture of the long bones in man, and is accounted for by the fact that the medulla of the osseous canal gains entrance into the ruptured blood-vessels, and is thus mixed up with the general circulation, becoming arrested in its passage through the pulmonary vessels, and there forming a block to the pulmonary circulation, which finally effectually stops the aeration of the blood, and causes death by aspnoea.

On comparing the fat condition of the body of this sheep to the emaciation of diabetic subjects, one cannot help being struck with the contrast between the two extremes. It is certainly difficult to answer the question, how is the fat produced in the blood of diabetic patients? But in this sheep the conclusion seems self-evident: that we had an animal which (along with others) had been fed up to such a point that it could no longer either assimilate, utilise, or excrete the highly nutritious matters contained in its food.

The Shropshire Down breed of sheep are noted for their fattening properties, and in this case we had an example of an animal having been fed beyond the point of perfection. The winter of 1881-2 was a remarkably open one; grass was plentiful
throughout the season, and, in addition to an abundance of grass, these sheep had a full allowance of turnips, besides corn and cotton cake. This rich food, the quantity of which, however, does not strike one as being outrageously great, given in addition to the turnips and grass to animals whose fattening qualities is so well known, was evidently too much. After feeding upon it, the sheep would have little or no inclination to roam about; indeed, grass being abundant, there would be no necessity for them to travel far in search of food; fat was consequently so rapidly formed that all the tissues of the body become loaded with it, and finally the blood, where it caused an obstruction to the circulation, and thus induced death.

SEPTICÆMIA—PROGRESSIVE GANGRENE.

Definition.—A condition produced by the absorption or introduction of putrescent matter into the system, characterised by great prostration, metastatic lameness, colicky pains, with purging, the faeces being foetid, factor of the breath, and rapid emaciation in the horse. In horned cattle and sheep it is generally seen after parturition, and manifested by great prostration, collapse, fluttering pulse, expulsion of a coffee coloured fluid from the uterus, violent straining, purging, and great restlessness; also known as braxy, affecting sheep in their first year (hoggie), and occurring in the late autumn and early winter months, especially when the weather is cold, and the grass covered with hoar frost. It is also very destructive to lambs, and to calves a few days old.

These varying forms of septicæmia will be found described under various heads in the context of this work, as well as in the Principles and Practice of Veterinary Surgery.

The artificial induction of Septicæmia has been the subject of various experiments—first of all by M. Davaine, and afterwards by M. Bouley, Director of the Alfort Veterinary School. The experiments were as follows:—Six watch-glasses were placed on a table. Into the first 100 drops of water were placed, and to these was added one drop of blood from a septicæmic rabbit; the whole was stirred so as to produce a solution of $\frac{1}{10}$. One drop of this was placed in the second glass containing 100 drops of
water, and a dilution of \( \frac{1}{10} \) produced. In the third glass, a drop from the second gave a dilution of \( \frac{1}{100} \). In the fourth glass a drop of third dilution added to the 100 drops of water produced a dilution of \( \frac{1}{1000} \). In the fifth glass, similarly treated, there was a dilution of \( \frac{1}{1000} \); and in the sixth a drop of the dilution gave a trillionth \( \left( \frac{1}{10^{12}} \right) \). Matters being so disposed, four rabbits were inoculated respectively with the first, second, third, and fourth dilutions, a horse with the second, and a guinea-pig with the first. Next day all the rabbits were dead, the guinea-pig fell ill, but recovered, and the horse sustained no harm. M. Bouley communicated an account to the Académie de Medicine of numerous experiments he had made confirming the above, and stated that dogs can also be killed by the septicæmic virus derived from the rabbit, and that such virus derived from the horse possesses much less virulence than that furnished by the rabbit.

I have repeatedly experimented on birds and rabbits with the undiluted blood of pyæmic—septicæmic (Vogel)—rabbits and birds, and have always induced death, either by a rapid corruption of the whole blood-mass, from which the animals have died in a few hours, or, resisting the first effects of the morbid inoculated material, from pyæmia with abscesses in various internal organs.

Selecting mice as being specially adapted for experiments on infective diseases, Koch has made some remarkable discoveries pointing to the conclusion that death may be induced by (a) a soluble poison, "Sepsin;" by (b) a true septicæmia induced by the multiplication of the bacilli introduced by the inoculation; and by (c) a progressive destruction of tissue (gangrene), commencing at the point of inoculation and spreading rapidly to adjacent parts.

Blood or meat infusion, which have putrefied for a short time, act more injuriously than when putrefaction has extended over a longer period, and five drops of such blood, if injected under the skin of the back of a mouse, kills it within a short time. There are marked symptoms of illness immediately after the injection. The mouse becomes restless, runs about constantly, but showing great weakness and uncertainty in all its movements; it refuses food, the respiration becomes irregular and slow, and death takes place in from four to eight hours.
In such a case the greater part of the injected fluid is found in the subcutaneous cellular tissue of the back in much the same condition as before it was injected. It contains bacteria of the most diverse forms, irreguarily mixed together, and as numerous as when examined before injection. No inflammation can be observed in the neighbourhood of the place of injection. The internal organs are also unaltered. If blood from the right auricle be introduced into another mouse, no effect is produced. Bacteria cannot be found in any of the internal organs, nor in the blood of the heart.

Koch therefore concludes that an infective disease has not been produced as the result of the inoculation, but that the death of the animal is due to a soluble poison—Sepsin—which has been shown by the researches of Bergmann, Panum, and others to exist in putrid blood. This supposition is confirmed by the fact that when less fluid is injected the symptoms of poisoning which follow are less marked, and are quite absent when one or at most two drops have been injected. After the use of such small quantities mice often remain quite well, but a third of them, on an average, become ill after the lapse of about twenty-four hours. The less amount of putrid fluid injected, the fewer mice become affected, but less than one drop is sometimes sufficient; thus, of twelve inoculated with one-twentieth to one-tenth of a drop each, only one was successfully infected.

The first symptoms of the success of the inoculation with this minute quantity is an increased secretion from the conjunctiva. The eyes appear dull, and a whitish mucus collects between the lids, and finally glues them together. At the same time lassitude sets in, the animal moves little and languidly; as a rule it sits quite still, with its back much bent and its extremities closely drawn up. It then ceases to eat; its respirations become slower; weakness gradually increases, and death comes on almost imperceptibly. Convulsions never precede it (they always do so in anthrax). After death the animal still remains in the sitting posture with its back strongly bent; whilst a mouse which dies from anthrax is always lying on its back or side, with its stiffened limbs fully extended. Thus, by the position of the body after death, a fatal result produced by the inoculation of putrefying blood is at once distinguished from that occasioned by inoculation with the material of anthrax.
On post mortem examination there is found at the place of injection or inoculation slight oedema of the subcutaneous cellular tissue. This, however, is often absent, and the internal organs, with the exception of a considerable swelling of the spleen, appear quite unaltered. One-tenth of a drop of the fluid of the subcutaneous oedema, or of blood from the heart of such animal, inoculated into another mouse, is sufficient to cause exactly the same symptoms, and death in about fifty hours. From this second animal a third may be injected, and so on through as many successive animals as one pleases.

Koch says that the certainty with which the infective material can be carried from one mouse to another is greater than in anthrax, as in the latter the material for inoculation must be taken from the spleen, because the blood of mice affected with anthrax often contains very few bacilli; but in septicæmia, produced by putrefying blood, it is a matter of indifference from which organ the material for inoculation is taken, and even the smallest quantity will produce an effect with certainty.

The blood of mice which became ill after injection of one to ten drops of putrefying blood was found to contain, as a rule, different varieties of bacteria in small numbers, micrococci, and large and small bacilli. If, however, the animals died after inoculation with putrefying or septicæmic blood, small bacilli alone appeared. This result was invariable, and the bacilli were in large numbers.

These bacilli are often attached to each other in septicæmic blood in pairs, either in straight lines or forming an obtuse angle. Chains of three or four bacilli also occur, but they are rare. They show at first sight a great resemblance to small needle-like crystals, but that they are undoubtedly vegetable bodies is evident, for when septicæmic blood is kept in an incubation apparatus, these grow in a manner similar to the bacilli of anthrax, not forming long threads like the latter, but dense masses, which consist of isolated bacilli sometimes containing spores. They are extremely difficult to see, and it is necessary to stain them with methylaniline violet or blue. The best way to do this is to dry the fluid containing them on a glass slide, stain with methylaniline, and mount the specimen in Canada balsam.

The relation of these bacilli to white corpuscles of the blood is peculiar. They penetrate into these and multiply in their
interior, and it is often found that there is hardly a single white corpuscle in the interior of which bacilli cannot be seen.

Disease induced by the inoculation of the blood of septicæmic mice cannot so successfully be induced in so many different animals as with that of anthrax. Thus Koch failed to cause it by inoculating rabbits, and even field mice resisted the inoculations.

Occurring along with the septicæmic bacillus, Koch has found in mice, after the introduction of putrefying blood, a micrococcus in the neighbourhood of the place of injection. This organism is of rapid growth, and forms very regular chains. As a rule, when an animal dies of septicæmia after about two days, none of the numerous forms of bacteria which were injected with the putrid blood can be discovered, except the septicæmic bacilli, or it may be a few residual specimens growing with difficulty. It must therefore be supposed that none of the other bacteria injected at the same time find in the body of the living mouse a suitable soil, and that they therefore die more or less quickly. Koch's attention was therefore arrested when he found in some cases, growing at and about the inoculated spot, micrococci in unusual abundance and of a constantly characteristic form. They were not present in the blood, and by inoculation with the blood the septicæmic bacilli alone were transmitted. In order to test whether they could be inoculated, it was necessary that the material should be taken from the place of injection. Inoculations carried out in this way were successful in producing both forms of disease, and the virulence of the serum from the subcutaneous cellular tissue containing these micrococci was just as marked as that of the septicæmic blood. When the point of a knife which had been well cleaned was merely brought in contact with the subcutaneous tissue at a spot about one centimetre and a half from the place of injection or inoculation, and when with this knife another animal was immediately inoculated, the inoculation was successful on every occasion. Septicæmia was of course always produced at the same time, because the serum used contained also septicæmic bacilli. The influence of these micrococci on animal tissues, and their mode of spreading, can be best traced on the ear of a mouse, and it is specially instructive to compare an ear on which only septicæmic bacilli have been inoculated with one
into which both the bacilli and the chain-like micrococci have been introduced. In the former the cellular tissue is full of red corpuscles and lymph cells, so that the bacilli can often be recognised only with great difficulty among the numerous cell nuclei. The other ear presents totally different appearances. Spreading from the place of inoculation, one can see extremely delicate and regular micrococci chains, here pressed together so as to form thick masses, traceable almost to the base of the ear, all the tissues of the part occupied by them being remarkably altered. As far as the micrococci extend, neither red blood globules nor nuclei of lymph or of connective tissue cells can be seen. Even the extremely resistant cartilage cells, and the plasma cells so richly present in the mouse's ear, and which are likewise characterised by great resisting power, are pale and scarcely recognizable. All the constituents of the tissue look as if they had been treated with caustic potash; they are dead, they have become gangrenous. Under these circumstances the bacteria develop all the more vigorously, and the micrococci penetrate in numbers into the damaged blood and lymphatic vessels, and here and there they fill them so completely that the vessels appear as if injected. Among these the septicæmic bacilli, no longer obscured by nuclei, are seen very distinctly in small groups, which are at times very dense, and can be traced up to the root of the ear, and indeed beyond it, having at the same time increased enormously in the blood, and ultimately causing the death of the animals. The micrococci, on the other hand, and the destructive process associated with them, have only extended during the same time (about fifty hours) as far as the vicinity of the root of the ear, where their limit is sharply defined, and can be seen on a longitudinal section examined with a low magnifying power (twenty-five diameters). The appearances presented by the ear on a post mortem examination lead to the conclusion that the action of these micrococci in causing gangrene is somewhat as follows:—Introduced by inoculation into living animal tissues, they multiply, and as a part of their vegetative process they excrete soluble substances, which get into the surrounding tissues by diffusion. When greatly concentrated, as in the neighbourhood of the micrococci, this product of the organisms has such a deleterious action on the cells that they perish and finally com-
plutely disappear. At a greater distance from the micrococci the poison becomes more diluted and acts less deleteriously, only producing inflammation and accumulation of lymph corpuscles. Thus it happens that the micrococci are always found in the gangrenous tissue, and that in extending they are preceded by a wall of nuclei, which constantly melts down on the side directed towards them, while on the opposite side it is as constantly renewed by deposition of fresh lymph corpuscles.

These observations refer to inoculations with fluid containing both micrococci and bacilli, and it might have been supposed that the septicæmic bacilli were necessary forerunners of the micrococci, and must to a certain extent prepare the way for them.

Koch attempted by various means to separate them from each other, but for a long time with no avail. But chance led him to the proper method. A field mouse, which he had already found out possessed an immunity from septicæmia, was inoculated with bacilli and chain-like micrococci. The experiment was made in the expectation that neither parasite would develop. This expectation, however, was not fulfilled, for, though the bacilli, as usual, underwent no development, the micrococci increased and spread in exactly the same manner as had been the case in the domestic mouse.

Beginning at the point of inoculation in the root of the tail, the gangrene spread onwards along the back, passing deeply among the dorsal muscles, and downward on both sides to the abdominal wall. The animal died three days after inoculation. The parts affected with the gangrene were partially denuded of epidermis and hair, and contained chain-like micrococci in extraordinary numbers. The same micrococci were also found on the surface of the abdominal organs, although there was no visible peritonitis. The blood and the interior of the organs were, on the other hand, quite free from them. From this animal other field mice, and from these again domestic mice in various successive series, were subsequently injected, and with always the like result—namely, that only chain-like micrococci, and in their train progressive gangrene, were obtained.

The development of bacteria even in a suitable soil can be checked by certain influences, physical, biological, and chemical, and of these none are more potent than temperature. No fully
developed bacteria have as yet been found to survive after long exposure to 60° C. when in the moist state, and but few resist a temperature 50° C. = 101° F.

The spores of bacteria, however, can resist a much higher temperature than that which destroys the adult organism, and all agree that the boiling-point of water is the lowest which can be relied upon to destroy spores; but in the dried state they are much less readily destroyed, requiring three hours’ exposure to a temperature of 140° C.

Again, intense motion checks bacterial life, but electricity seems to have no effect upon them.

Of the chemical influences which destroy or retard bacterial life the most powerful is corrosive sublimate, its action being instantaneous even in a dilution of one part to five thousand. Next to the bichloride are placed bromine, iodine, and chlorine; but carbolic acid is not so reliable, as nothing less than a three per cent. solution destroys spores, and requiring at least seven days, and a five per cent. solution requiring from twenty-four to forty-eight hours. When dissolved in oil, Koch says it is harmless both to spores and developed bacteria. When immersed in it in the dried state and dissolved in alcohol, it is also inert.

The only other agents which can be depended upon to destroy microbial life in less than twenty-four hours are permanganate of potash in five per cent., and caustic acid one per cent. solution. A five per cent. solution of chloride of iron destroys within six days, but neither sulphate of copper nor chloride of zinc seem to have any effect.
CHAPTER XII.

PATHOLOGY—continued.

MODES OF DEATH.

Following the example of Dr. Williams, Sir Thomas Watson, and other writers upon medicine, I purpose very briefly to consider the chief varieties of the modes of death.

An inquiry into this subject, says Watson, "is not one of merely curious interest, but has a direct bearing upon the proper treatment of disease. It will teach us what we have to guard against, what we must strive to avert in different cases."

A continuance of "life is inseparably connected with the continued circulation of the blood. So long as the circulation goes on, life, organic life at least, remains. When the blood no longer circulates, life is presently extinct; and our investigation of the different modes of dying resolves itself into an investigation of the different ways in which the circulation of the blood may be brought permanently to a stand.

"Observe the ample provision that is made in the construction of the body for carrying on and maintaining this essential function. First, there is an extensive hydraulic apparatus distributed throughout the frame, consisting of the heart and other blood-vessels. Next, there is a large pneumatic machine, forming a considerable part of the whole body, composed of the lungs and the case in which they are lodged. Lastly, the power by which this machine is to be worked and regulated is vested in the nervous system. Each of these systems must continue in action, or the circulation will stop, and life will cease. The functions they respectively perform are consequently called vital functions; and their main organs—the heart, the lungs, the brain—are denominated vital organs.
The functions of any one of the three being arrested, the functions of the other two are also speedily extinguished."—

(WATSON's Principles and Practice of Phys.)

Death, it is observed, occurs as follows:—

1. Death beginning at the heart—syncope—asthenia.
2. " " " lungs—apnoea.
3. " " " brain—coma.
4. " " " blood—necromia.

DEATH BEGINNING AT THE HEART.

Death beginning at the heart may occur in two ways:—1st. Suddenly, or by syncope; and 2d. By a gradual cessation of the heart's action. Syncope may occur in two ways:—1st. By the heart losing its irritability, so that it ceases to contract—asthenia; and 2d. By tonic spasm, in which it remains rigidly contracted. Death from tonic spasm of the heart is rare amongst the lower animals. I have, however, seen one instance, where a valuable horse died from this cause in consequence of a sudden fright.

In both these cases death is instantaneous. In the first case, each chamber of the heart is found after death to be filled with its proper kind of blood, upon which it has been unable to contract. Sir Benjamin Brodie, in some experiments recorded in the Philosophical Transactions for 1811 and 1812, found that when death was occasioned by the upas antid, that the heart was full after death, with purple blood in its right and scarlet blood in its left cavities. This proves that the heart has ceased to contract upon the contained blood. In the second case, the heart appears very small and hard, the ventricles, particularly the left, firmly contracted and containing no blood, and the heart substance very firm. This state of the heart was supposed to depend upon concentric hypertrophy, but its true nature was pointed out by Cruveilhier and Dr. G. Budd. Should any doubt remain as to its true nature, if the heart be kept for a few days, it will, if the condition be that of spasm, lose this tonicity, and may easily be restored to its regular dimension by a little manipulation. Both conditions of the heart—namely, loss of irritability and tonic spasm—may arise from similar causes. Shock, for example, may produce the one or the other
condition; and wounds of the heart are sometimes followed by paralysis, sometimes by rigid contraction of that organ. In sudden death from drinking very cold water when the body is heated, the heart has been found contracted.

In the slower modes of death beginning at the heart, it is found that the same conditions exist after death. In death from haemorrhage—anaemia—it is found that the heart is firmly contracted, if the animal be examined shortly afterwards; the circulation failing, not because the heart has lost its power of contraction, but because blood does not arrive in sufficient quantities in its cavities. That the heart does not lose its power of contraction in such cases is proved by the transfusion of blood from an animal into the veins of a human being or other animal apparently dead from haemorrhage, where it has been found that animation may thus be restored. "It is quite clear," says Watson, "that this introduction of fresh blood could be of no avail in a case where the heart was unable to act upon the blood which had already reached it."

Approaching death from haemorrhage is manifested by great and rapidly increasing pallor of the mucous membranes, coldness of the mouth, surface of the body, and extremities, cold sweats, a dazed or dim appearance of the eyes, convulsive struggles—if the animal is down, at first strong but rapidly becoming feeble, if standing, the animal will balance its body upon the extremities; the pulse feeble, irregular—sometimes slow, sometimes fast—cold breath, convulsive breathing, dilatation of the pupils, and very often just before death the animal gives a loud scream or delirious neigh.

In another form of gradual death beginning at the heart, it is found that the heart has gradually lost its power of contractility. This is the most common mode by which death occurs, and is the termination of many exhausting diseases, especially those which destroy the strength without directly interfering with the more vital functions, such as influenza, diarrhoea, diabetes, fevers, as well as inanition from want of food, or other causes which reduce the powers of the whole body.

The two conditions of the heart found after death beginning at that organ may each be brought about in two ways:—1st. Suddenly, as in instantaneous death from shock or great violence; and 2d. When death, although it may be said to occur suddenly,
presents some symptoms of its approach, however brief those symptoms may be, as from hemorrhage, the operation of some poisons, as aconite, hydrocyanic acid, upas antiar, tobacco; from lightning, electricity, and various animal poisons, as snake-bites; the operation of debilitating influences, as well as diseases which tend to weaken and paralyze muscular force, and to produce asthenia.

In death from gradual asthenia the pulse becomes very feeble, frequent, and often irregular; the respirations feeble, sometimes sighing; the muscular debility extreme. Pallor of the membranes comes on gradually, or in some cases they may present an unhealthy reddened or brownish-red appearance from the blood remaining in the veins, the extremities become cold, and cedematous.

In various wasting diseases, such as pleuro-pneumonia-bovina, diarrhoea, polyuria, or any disease which more gradually exhausts the powers of life, death is caused by anemia and asthenia. The blood gradually diminishes in quantity and deteriorates in quality, therefore the supply to the substance of the heart becomes diminished, and in a condition unsuited to nourish the heart properly. The power of the heart, as well as of the muscles generally, is gradually lessened, and at length ceases altogether; and when death is so produced the heart is not contracted and empty as in death from anemia, nor so full and engorged as in death from asthenia. This form of death is called by Watson death by inanition, and its typical form is that occurring from starvation.

DEATH BEGINNING AT THE LUNGS.

By this it is meant that the function of breathing is the first to fail, improperly termed death from asphyxia—literally pulselessness—more correctly termed death by apnæa, privation of breath, or suffocation.

This form of death is caused by diseases of the lungs or bronchial tubes, pleurisy terminating in hydrothorax, where air is prevented from entering the lungs by the pressure of the pleuritic fluid, mucus, pus, or blood, filling the tubes and air cells; by laryngitis, spasm of the glottis, or when tumours press upon the larynx or trachea; by oedema of the glottis; diseases of the
heart affecting the quantity of blood in the lungs and great thoracic vessels; strangulation; drowning; pressure upon the diaphragm, forcing it forward and preventing admission of air into the lungs, as in severe tympanitis of the stomach and bowels, or from any circumstance which may paralyze the diaphragm—fracture or dislocation of the upper cervical vertebrae, and pithing, for example—or obstruct the passage of air through the nostrils, larynx, trachea, or bronchial tubes.

Sudden death from apnea is not often witnessed as the result of disease, but is generally brought about by accident or design, accidentally when the upper cervical vertebrae are fractured or displaced; in cases of parturient apoplexy, when fluids gain entrance into the lungs, and from impaction of foreign bodies, or polypi in the larynx; and designedly, when an animal is pithed. Death is also thus produced by the entrance of air into the veins.—(See Principles and Practice of Veterinary Surgery.)

Death from apnea takes place most commonly from the supply of air being gradually cut off by morbid changes in the respiratory organs, and is often accompanied by asthenia and coma; but generally the symptoms belonging to apnea are plainly predominant. In death, when the passage of air into the lungs is arrested suddenly and completely, it has been observed that the muscles of respiration exhibit strong and violent contractions; that the efforts to breathe are very great, struggling but ineffectual, and very distressing. This extreme distress, however, soon passes away, and is succeeded by vertigo, stupor, loss of consciousness, and convulsions, till at length all efforts cease, except a few irregular twitchings of the limbs; the muscles then relax, the sphincters yield, but even then the movements of the heart and the pulse continue for a short time after all signs of life are gone. The other signs of this method of death are congestion and lividity of the visible mucous membranes, a full, staring eye, protrusion of the nose, dilatation of the nostrils, and sometimes flapping of them. When it arises from inflammation or spasm of the muscles of the larynx, tumours, abcesses, or obstruction in the trachea, there will be a loud, roaring, inspiratory sound. In the slower forms of apnea, from diseases of the lungs, air tubes, or hydrothorax, where the interruption is less complete, the efforts less violent, the congestion of the membranes less marked, there may be little
perceptible protrusion of the nose; indeed, in bronchitis, stupor is present to such a degree that the animal generally hangs its head. The functions of the body together gradually failing, the symptoms of suffocation are less decided.

The pathology of this mode of dying is now pretty well understood. Bichat made several experiments which went to prove that unaërated blood not only reached the left side of the heart, but was sent to all the arteries of the body.

His experiments were as follows:—A ligature was applied to the trachea of a living animal; a small opening was then made in one of the carotid arteries. Presently the slender stream of blood which issued began to lose its arterial tint, and to assume the dark colour of venous blood; but, contrary to what had been previously supposed—namely, that the circulation would be immediately arrested in the lungs, the quiescence of the lungs, consequent upon the cessation of the alternate movements of the thorax, forming a mechanical impediment to the transit of blood through them (Haller), or that the unaërated blood passed through the lungs and entered the left auricle and ventricle, but went no farther (Dr. Godwin)—Bichat discovered that the blood continued to flow from the opened carotid, and that its afflux upon the brain was marked by convulsions and insensibility. This led him to believe that the blood underwent no obstruction in its passage through the lungs, but that, remaining unpurified and venous, it acted as a poison upon every part to which it was carried by the arteries—first upon the nervous system, and ultimately (passing through the coronary arteries) upon the muscular substance of the heart itself. "There are, however," says Watson, "two well-known facts upon which this theory is inexplicable—the comparative emptiness of the left chambers of the heart, and the restoration of the suspended functions by the timely performance of artificial respiration. The air could never reach and revivify or depurate the venous blood stagnating in the capillaries of the heart." Sir James Kay Shuttleworth, in his work on Asphyxia, and later, Mr. Erichsen, in the Edinburgh Medical and Surgical Journal, have endeavoured to prove that stagnation of the blood commences in the pulmonary capillaries, that the stagnation is due to its non-arterialization, and that the movements of the left side of the heart are brought to an end principally by the deficient supply of blood from the lungs.
Venous blood (say these observers), circulating through the arteries, has no directly poisonous operation, but is capable, though much less effectually than arterial blood, of supporting in some degree the irritability of the muscles; and it appears that the primary and main cause of the failure of the circulation seems to be the difficulty with which the non-arterialized blood passes through the capillaries of the lungs, and partly the imperfect stimulus afforded by the venous blood to the walls of the heart, as well as its incapability to support the functions of the brain and nervous system. The appearance of engorgement of the pulmonary arteries and venous system generally, with distension of the right side and comparative emptiness of the left side of the heart, seen after death, are more constantly visible in the slower forms of apnoea than after sudden suffocation; for after sudden death blood seldom coagulates, and if the animal is not shortly examined, the engorgement is apt to disappear by gravitation.

The conclusions of Sir James Kay Shuttleworth and of Mr. Erichsen, although correct enough, fall rather short of a full explanation; for it has been ascertained by many observers that when an animal is strangled by a tight ligature on the trachea, and examined immediately after death, the lungs are always found void of blood, whilst the pulmonary artery, up to its smallest branches, the great veins and the heart, are greatly engorged. Dr. George Johnson, in explaining this, says that some opposing power is brought into play, more than equal to the propelling power of the heart, and that this opposition is due to the firm contraction of the muscular walls of the ultimate branches of the pulmonary artery. He calls this contraction the stop-cock action of the ultimate pulmonary arteries. Dr. Johnson proved by experiments of his own that this condition exists whether the ligature be applied after or before a full inspiration; whether the lungs were at the time full or comparatively empty of air. "These," says Watson, "are the plain and unquestionable facts of the case. They show that some opposing power must have been called into play more than equal to the propelling power of the right ventricle of the heart. Now, such a power—and it is the only conceivable one—actually exists at the very place where the venous current meets with its curb, and it consists in the firm contraction of those muscular
fibres of the minute arteries, the function of which is to regulate
the blood supply in accordance with the varying requirements
of the part. This function again is determined by those un-
sleeping sentinels the (vasa-motor) nerves. Were it allowable,
for the sake of illustration, to impersonate the vital forces con-
cerned in this marvellous adaptation, we might liken the process
to the intelligent stopping of the traffic on an obstructed line of
railway by a backward telegram."

In order to test the correctness of Dr. George Johnson's
experiments, I have repeatedly examined strangled dogs, and
found that the heart will continue to beat for more than three
minutes after the respiratory efforts have ceased, and that the
lungs and great vessels are always as he has described them,
namely, the lung substantes pale and empty, the pulmonary
artery and right side of the heart, with the cææ, immensely
engorged, and the pulmonary veins and left side of the heart
containing a small quantity of venous blood. From these expe-
riments it appears very conclusive that death by apnoea occurs in
two ways, and that two distinct pathological conditions of the
lungs are observable after death:—1st. When death is sudden,
as from suffocation by strangulation, drowning, or any cause
whereby the supply of air is suddenly cut off, the stop-cock
action of the ultimate pulmonary arteries prevents the blood
from flowing in its ordinary quantity to the pulmonary capil-
laries, veins, and left side of heart, and that the lungs are pale
when examined immediately after death: 2d. When death more
slowly occurs, the blood accumulates in all the vessels of the
lungs, which after death appear engorged, congested, and black.
This is the condition of the lungs seen when an animal is
galloped to death, in pulmonary apoplexy, and congestion; and
in death from some acute diseases, where towards the close of
the disease the heart becomes too enfeebled to propel the blood
through the intricacies of the pulmonary system, or when the
blood itself becomes so altered as to be incapable of proper
arterialization.

To prevent death by apnoea, it is obvious that the respiratory
function must be restored where it is defective, that all impedi-
ments to the passage of pure air into the lungs must be removed.
The subject of treatment will, however, be considered in another
place, and I may merely state here that nothing has been found
so effective and so useful in balancing the circulation and in
restoring the passage of blood through the lungs as the applica-
tion of heat to the whole body, frictions, stimulating applications
to the extremities, warm clothing, and bandages, in addition to
abundance of pure air for the animal to breathe, and that blood-
letting frequently affords apparent relief.

DEATH BEGINNING AT THE BRAIN.

Death by coma, or beginning at the brain, is much less com-
monly witnessed in the lower animals than death by apnoea or
by asthenia. Such diseases, however, as parturient and idiopathic
apoplexy, cerebral meningitis, and other allied affections, which
act upon and destroy the functions of the brain, cause death in
this way. Death by coma is also induced by certain narcotic
poisons, such as opium, as well as by inordinate quantities of
effete materials in the blood, more especially urea and carbonic
acid; by fractures of the cranial walls, the pressure of tumours,
abscesses, serum or extravasated blood, and by coagula in the
cerebral arteries, obstructing the flow of blood, and causing
anaemia of the cerebral mass.

The symptoms of coma are stupor, insensibility, suspension of
voluntary motion, which come on sometimes suddenly, as in
apoplexy and injuries of the head, whilst in other cases they
supervene gradually. The breathing becomes slow, irregular,
sterorous; the instinctive motion of breathing still continues,
but all voluntary attention to the act is lost. The feeling of the
want of air is still sufficiently strong and powerful to excite,
through the medium of the pneumo-gastric and branches of the
fifth nerves, the reflex power of the medulla oblongata to sustain
the involuntary movements of the thorax; but at length this
fails also, the chest ceases to expand, the blood is no longer
aerated, and thenceforward precisely the same internal changes
occur as in death by apnoea.—(Watson.)

Coma ultimately destroys life in the same way as apnoea,
with this difference, that in death by apnoea the aeration of the
blood and the functions of the lungs cease first—the circulation
of the non-arterialized blood destroying the functions of the
brain; whilst in coma the functions of the brain cease first, and
in consequence of the loss of nervous power, the movements of
the chest and the aeration of the blood cease also. The post
mortem appearances of death by coma and of that by apnoea are
the same, except, indeed, in those cases where the cause of the
coma remains, when it will be present in addition to those of
apnoea. Reasoning upon the conclusion that the circulation
cesses consequent upon the cessation of the act of respiration,
arising from suspension of the nervous power, Sir Benjamin
Brodie was led to think that by continuing respiration artifi-
cially in animals labouring under narcotic poisons, the circulation
of the blood might be kept up until the effect of the poison upon
the brain had passed off. The correctness of the supposition he
soon verified by experiment. He inserted some woorara into a
wound which he had made in a young cat: this after a short
time entirely destroyed the respiratory movements, and the
animal appeared to be dead, but the heart could still be felt
beating. The lungs were then artificially inflated about forty
times a minute. The heart continued to beat regularly. When
artificial respiration had been kept up for forty minutes, the
pupils of the cat's eyes were observed to contract and dilate
upon the increase and diminution of light, but the animal
remained perfectly motionless and insensible. At the end of an
hour and forty minutes there were slight involuntary contrac-
tions of the muscles, and every now and then there was an effort
to breathe. At the end of another hour the animal, for the first
time, showed some signs of sensibility when roused, and made
spontaneous efforts to breathe, twenty-two times in a minute.
The artificial breathing was, therefore, now discontinued. It
lay as in a state of profound sleep for forty minutes longer,
when it suddenly awoke and began to walk about. It must
be clearly understood that artificial respiration can be beneficial
only where there is a suspension of the nervous functions, as in
cases of poisoning, and not where there is destruction of them
by disease, injury, or the long-continued action of poisons.

Professor Sewell experimented upon the horse with the
woorara poison, and found that by artificial respiration life
could be maintained until the action of the poison had passed
away, and that afterwards the animal regained consciousness
and recovered from its effects.
DEATH BEGINNING WITH THE BLOOD.

Necæmia, or death beginning with the blood.—In rinderpest, splenic apoplexy, black-quarter or quarter-ill, braxy, purpura haemorrhagica, and scarlatina, death may be said to be due to the death and decomposition of the blood, the action of the heart ceasing because the blood is no longer capable of affording the necessary stimulus.

At an early stage of these diseases, when they occur in their worst form, the blood exhibits changes in its composition, manifested by petechiae and vibices on the skin and mucous membranes, extravasations into the subcutaneous and muscular tissues, and by congestion of, and haemorrhages into, the internal organs.

The blood is fluid, of a dark colour, and possesses septic properties, as manifested in its deleterious operations on other animals and on man.—(See Malignant Pustule.) It decomposes rapidly, and wherever a spot of extravasation—ecchymosis—may be found, there, almost simultaneously with the extravasation, will the presence of a gas, resulting from the decomposition of the blood, be detected, whilst a peculiarly putrid odour is exhaled from the surface of the body, and from the excretions.

"The blood," says Dr. Williams, "the natural source of life to the whole body, is itself dead, and spreads death instead of life. Almost simultaneously the heart loses its power; the pulse becomes weak, frequent, and unsteady; the vessels lose their tone, especially the capillaries of the most vascular organs, and congestions occur to a great amount; the brain becomes inactive, and stupor ensues; the medulla is torpid, and the powers of respiration and excretion are imperfect; voluntary motion is almost suspended; secretions fail; molecular nutrition ceases; and, at a rate much more early than in other modes of death, molecular death follows close on somatic death—that is, structures die, and begin to run into decomposition as soon as the pulse has ceased; nay, a partial change of this kind may even precede the death of the whole body (Somatic Death—Dr. Pritchard); and the fetid aphthous patches in the throat, the offensive colliquative diarrhoea of persons in the last stage of various fatal diseases, parts running into gangrene, as in the carbuncle plague, the sphacelous throat of malignant scarlatina, and the sloughy sores of the worst forms of typhus, and in the large
intestines in dysentery, and the putrid odour exhaled even before
death by the bodies of those who are the victims of similar
pestilential diseases—are so many proofs of the early triumphs of
death over vital chemistry."—(Williams' Principles of Medicine.)

This mode of death is not recognised by some writers, but
the truth of the above quotation will, I have no doubt, strike
many who have witnessed the course and progress of the blood
diseases of the domesticated animals; the extensive congestions
and extravasations of black, tar-like blood, and its rapid decom-
position in splenic apoplexy and quarter-ill; the gangrenous
throat, and sphacelated patches of skin in purpura haemorrhagica
and scarlatina; the putrid odour of the secretions and the
aphthous patches of rinderpest, and the very general advent of
an exhaustive diarrhoea in those cases which do not succumb to
the shock of the disease; the peculiar odour exhaled, as well as
the rapid decomposition of the whole body after death;—indeed
it may truly be said that decomposition of the blood has set in
prior to death in many instances, for if the blood be immediately
examined under a high microscopic power, vibriones may be
found in great abundance.

The symptoms of the approach of death by necromia are
generally as follows:—A dusky livid colour of the visible mucous
membranes; slight exanthematosus patches on the skin, petechial
spots—in rinderpest these were thought to be small-pox
pustules—or extensive extravasations and the production of a
fetid gas subcutaneously; oozing of a thin sanguineous fluid from
the nostrils or intestinal canal, or of blood in a semi-coagulated
condition, extreme prostration of strength; the pulse accelerated,
feeble, soft, sometimes presenting a double beat; twitches of
the limbs; dilatations of the pupils, the eye often fixed and
staring, but sometimes with the lids closed; unequal and
frequent respirations; cold perspiration, and a gradual fall of the
animal temperature. The horse will generally stand until the
last, and will only fall from prostration; it will then struggle in-
effectually to rise. The cow and sheep, however, will lie down in
the earlier stages of disease, and scarcely ever struggle to rise.

The prognosis in all diseases which tend to terminate in
necromia is seldom or never favourable, but it is generally con-
sidered expedient to endeavour to avert the tendency to a fatal
termination; and there are certain considerations which may be
useful guides to the practitioner to effect this end—namely, 1st. That such diseases tend to cause congestions of some organ or organs, as the lungs, spleen, stomach, and bowels, and consequently means should be taken to prevent as much as possible the occurrence of such congestions by removal of the patient from the contamination of foul air or bad drainage, and the avoidance of gastric or intestinal irritants. 2d. That the blood to a varying extent loses its plasticity, and is apt to exude through the walls of the vessels into the looser and softer tissues, and there undergoing rapid decomposition, gives gangrene of the tissue with which it is in contact, as in black-quarter, &c.

Means must therefore be taken to overcome this condition of the blood-mass by the administration of the chlorate of potash, which has a remarkable effect in restoring both colour and plasticity to the altered blood; oil of turpentine, which is not only a most valuable antiseptic, but is also a styptic, and in virtue of its diuretic properties assists the kidneys in the removal of effete materials. Quinine, the mineral acids, and the salts of iron will be useful at a later stage, should convalescence be established. Ammonia and its salts are to be avoided, as they tend to decrease the blood’s coagulability. Eggs, milk, and, as some recommend, beef tea, may, however, be administered in the earlier stages of the maladies, and continued until there be a return of appetite.
CHAPTER XIII.
PATHOLOGY—continued.
CLASSIFICATION OF DISEASES.

A correct classification of diseases, at once simple and suggestive, is a subject of profound importance, essential to the existence of veterinary science, and necessary for its teaching; and were the veterinarians of Europe to assemble in a great congress, and there agree upon a system by which diseases might be named, defined, enumerated, and classified, they would indeed attain a great object. At the present time, however, the science of nosology is very unsatisfactory as applied to the diseases of the domesticated animals, and incomplete even in the science of human medicine.

In a work of this kind it is necessary that I should refer to the efforts of physicians to arrive at a satisfactory system of nosology, and by reading books on medicine it will be found that diseases have been classified in different ways. In the system of Sauvages diseases were divided into ten classes—vitia, febres, phlegmasiae, spasmi, anhelationes, debilitates, dolores, vexamin, fluxus, cachexia. Linnaeus, Vogel, and Sagar’s classifications were also of this kind, and Cullen’s method was an unnatural simplification of it, by which all diseases were arranged in four classes—pyrexiae, neuroses, cachexiae, and locales. This system of classification is based upon the symptoms, and regards them as the essences of diseases; hence it is exceedingly unsatisfactory, and has been abandoned.

Believing that nosology should be founded upon correct pathology, Pinel divided diseases into five kinds, namely, fevers, inflammations, hemorrhages, neuroses, and organic affections. This classification is necessarily imperfect from the state of pathological science in Pinel’s days, but it approaches very
nearly the standard of a pathological nosology; was further developed by Bichat, and adopted by Dr. Craigie in 1836.

The results of modern investigations into disease prove that many ailments hitherto supposed to be merely functional are in reality accompanied by organic alteration of tissue; and it is not unreasonable to suppose that many of the so-called functional diseases will be found to depend upon an alteration of structure, and even where no organic change can be detected in cases where the existence of disease cannot be doubted, we may attribute our failure to the imperfection of our means and instruments of investigation, or our modes of using them.

Dr. Aitken, to whose works the reader is referred for further information, observes that "a perfectly philosophical or natural system of classification aims at having the details of its plan to agree in every respect with all the facts as they exist in nature, and to be, as it were, a 'translation of the thoughts of the Creator into the language of man.' To effect this end, arrangements, as they naturally exist, require to be traced out, not devised. The tracks in which such a pursuit must be followed up, and in which our knowledge is as yet deficient, may be shortly indicated under the following heads, namely:—

"(1.) The affinities or alliances of diseases with each other. (2.) The morbid anatomy of diseased parts. (3.) The communication, propagation, inoculation, generation, development, cause, and spontaneous natural termination of diseases. (4.) The connection of the phenomena recognised during life with the facts of morbid anatomy. (5.) The geographical distribution of diseases. (6.) The succession of diseases, as far as they can be traced through past ages; the peculiarities they have exhibited at different periods in the world's history, or within comparatively recent cycles of years.

"But the time has not yet come for a classification on a basis so comprehensive, simply because the material does not exist; and attempts to make so-called natural systems of arrangement must end in disappointment, on account of the uncertain and fluctuating data on which they must be based."
affected, or anatomically, according to the parts which they invade. The simplest plan, however, seems to me to be that adopted by Reynolds, namely, the division of diseases into two great groups.

The first group includes those diseases in which the whole organism appears primarily and prominently deranged, and the second group those diseases in which special organs or systems of organs are in like manner affected. The first group is divided into two classes:—A, those in which the disease appears to be developed by causes operating from without; and B, those in which it depends upon change within the body. In the first class we have those diseases which are caused by atmospheric influences, contagion, and other external causes; and in the second, hereditary diseases, rheumatism, tubercle, rickets, and other obscure bone diseases.

The second group, or that in which special organs are diseased, is again subdivided into many classes, consisting of diseases of systems of organs, such as—A, diseases of the nervous system; B, diseases of the digestive system and its appendages; C, diseases of the circulatory system; D, diseases of the respiratory system; E, diseases of the urinary system; F, diseases of the reproductive system; G, diseases of the locomotive system; and H, diseases of the cutaneous system.
CHAPTER XIV.

PATHOLOGY—continued.

CONTAGION AND CONTAGIOUS DISEASES.

A CONTAGIOUS DISEASE may be defined to be a morbid condition of the animal body, induced generally by the operation of a specific virus, termed a poison, derived from an animal similarly diseased, and communicated either by inoculation, contact, or through the medium of the air. Sometimes, however, contagious diseases originate otherwise than from infection, or, in other words, from causes other than those emanating from the bodies of diseased animals, as will be proved in the following observations. Some diseases are communicated by inoculation only; but, as a general rule, contagious diseases are communicable by contact, inoculation, and infection, i.e., by diffusion of the specific material through the air. All exceptions to this general rule will be pointed out as each contagious affection is described. The manner in which contagious diseases originate is a matter of much speculation and controversy, and has led to much interesting discussion. The observations of some pathologists lead them to the conclusion that the spontaneous origin of specific disease-poisons rests on negative evidence only; that evidence being the fact that cases do spring up in which it is impossible to trace the disease back to its source of propagation and dissemination. Thus, cases constantly arise which appear to give countenance to the sporadic origin of specific diseases, and the evidence, negative as it may be, is a very strong proof in favour of spontaneous origin. The subject is so interesting

1 By "spontaneous origin" is meant that a disease which may become contagious may originate in certain conditions of the animal body itself; from food, air, or other inanimate surroundings; but it is not intended to convey the idea that certain micro-organisms now found in diseases originate otherwise than from pre-existing ones.
and so important to the animal pathologist, that it is essential that both sides of the question should be placed before him.

Dr. Aitken, in dealing with epidemic influences which cause disease, says—"1st. That the specific poisons by which the communicable diseases, such as small-pox or typhoid fever, propagate their kind are never totally in abeyance. 2d. The specific communicable diseases are constantly extant somewhere, and only under conditions favourable to their dissemination do they spread or become epidemic. Although their germs, specific gases, active principles, or media of propagation and development may lie dormant or latent for a time, it is not to be inferred that they have ceased to exist. 3d. The history of all the specific communicable diseases demonstrates the same alternations of slumber and activity, of widespread prevalence in one place, while neighbouring places may remain free, and, finally, the same successive invasion of neighbouring places, so that the prevailing disease only begins to prevail in the new locality after it has already died out in the old. 4th. One element remains constant in the history of endemic influence, and that is the specific morbid poison which is the origin of each case. It is susceptible of transmission from place to place, gathering strength as it proceeds, again to die out or become dormant, so that its track is with difficulty followed or traced out. 5th. In large cities such specific poisons are always more or less active, and their diseases always present; but in the country districts they only now and then occur. The occurrence of long intervals of rural exemption is not traceable to any feebleness of the poison to act; for when the disease does become developed in these places, the ratio of persons or of animals attacked is incomparably greater than is ever seen in cities under like circumstances. 6th. In large towns the sewers are constantly charged with the materia morbi of specific diseases always abounding in towns. In small villages, and other places where no sewers exist, the air only may be infected, or the water contaminated, by the direct or indirect importation of cases of specific disease or their equivalents—the poison itself—so that the organic impurities, the dung-heaps, the open soil which surrounds the dwellings of the patients, the cesspools and the privies common to several houses, gradually but eventually become impregnated with the specific poison of the disease. Thus the atmosphere of the village may become
incomparably more virulent than the atmosphere of the sick-
chamber itself. Hence the rapid epidemic spread of the miasm-
atic diseases in the limited space of rural villages, and which
gives rise to the popular error that such diseases are invariably
contagious in country places, and only rarely so, or by exception,
in cities or large towns. 7th. All these specific diseases multiply
their kind after similar modes of propagation. 8th. All of them
establish a constant series of morbid changes and lesions, and
always issue in the reproduction of their own specific germ,
miasma, gas, morbid poison, or active principle by which they
propagate their kind. Thus small-pox propagates small-pox;
measles multiplies measles; scarlatina reproduces scarlatina;
typhoid fever breeds typhoid fever; typhus, typhus, and so on.
In the terse language of Dr. William Budd—'What small-pox
and measles were in the Arab in the days of Rhazes they still
are in the London Cockney of our own time. What they are
in the London Cockney they are in the wild Indian of the North
American prairie and in the Negro of the Gold Coast. To all
the other specific communicable diseases, as far as our records
go, the same remark applies. In races the most diverse, under
climates the most various, age after age, through endless genera-
tions of man, these diseases pass down through the human body
(sometimes through animals—e.g. ovine small-pox ?), perpetu-
ating their own kind, and each maintaining its separate identity
by marks as specific as those which distinguish the asp from the
adder or the hemlock from the poppy.' Such being the
case, it is difficult to conceive (as Dr. Watson and William
Budd most justly observe) 'that diseases of whose propagation
this is the history can ever be generated in any other way.' Most
of these miasmatic diseases also are peculiar to man, while
animals on their part are invested by a whole brood of com-
unicable diseases no less specific in their kind, each distinct
from the other, and most of them, although some may be com-
nunicable to man, are incapable of multiplying in the human
body. Cattle appear to be subject to a variety of malignant
and communicable fevers from which man is altogether exempt.
9th. Certain receptive conditions, or a predisposition (the nature
of which is unknown), exists in individuals, which appear
essential to the development of the specific poisons and the
establishment of the disease, and immunity against a repetition.
of the disease is generally conferred by one attack of the same disease, an immunity which has been proved by experiment on an enormous scale with regard to small-pox; and with regard to the other diseases of this kind, the belief in such immunity is deduced from extensive observation. But the immunity acquired by one attack of any of these diseases is of no avail against the rest. Measles, for example, renders the body proof against measles, but leaves it as open to small-pox as before, and so on of the rest. 106A. With regard to fermentation, putrescency, or decomposition, there is some reason to believe that it may quicken the activity or facilitate the development of specific morbid poison in the way of a predisposing cause. Dr. Budd, however, believes that this effect has been much overrated."

And, again, the most recent observations greatly strengthen this view of the origin of specific disease, inasmuch as an organism is developed in them, and which has the property of inducing the same disease in healthy animals. Some pathologists, however, maintain—and I am much inclined to support their conclusions—that a non-infective fever may so change in its type as to become infective, as, for example, where fevers of malarious origin have by overcrowding of the patients so changed their types as to become under such circumstances personally communicable.

It is now beyond doubt that miasmatic or malarial fevers are induced by the introduction of saprophytic germs into the body. Tommasi Crudeli of Rome and Klebs of Prague have shown that the lower strata of the atmosphere, surface soil, and stagnant water of the Roman plains contain micro-organisms of the bacillus type, which they have cultivated in various kinds of soil, and with which they have inoculated healthy dogs. In all the animals thus inoculated, malarial fever, which ran its course, producing enlargement of the spleen, as seen in man, was developed, and in the spleens the *Bacillus malaris* was found in great quantities, and Crudeli, as well as other physicians, has detected *Bacilli malaris* in the blood of human patients during the invasion of the fever.

Under ordinary circumstances, a malarial fever—ague—although caused by a saprophytic germ, is non-infective; and, as Dr. Carpenter says, no one thinks of an ague being "caught,"
like measles or scarlet fever, and even the most pernicious forms of remittent fever are believed, by those who have had large opportunities for observation, to be non-infectious. The reason, says the same authority, seems to lie in this, that the home of the "saprophyte," which gives rise to malarious disease, is the earth, in which it breeds and multiplies, whilst in the animal body it is a parasite, which does not ordinarily find in it the conditions for its full development, and produces no crop, though it may keep a feeble vegetable action, as there seems to be "something" wanting, under ordinary circumstances, to complete the maturation of the germs or to effect their elimination from the body in an infective form. This "something," however, appears to be supplied by overcrowding of the patients thus affected; for it is a well-established fact that fevers of a malarious origin may change their type under such circumstances, and thus become personally communicable. And this does not seem difficult to explain; for overcrowding means deficient air supply, and deficient air supply means deficient oxygenation of the blood, producing an accumulation in the circulating current of those "waste" products which are normally eliminated as fast as they are poured into it; and this accumulation of waste products, furnishing the pabulum for the development of disease germs, and changing their character from non-infective to infective, accounts for the transformation of a disease, non-infective under ordinary circumstances, into a virulent and infective one.

The above reasons seem to me to explain very clearly the origin of other infectious diseases; for if it is possible for an ague to become virulent and infectious by overcrowding of the patients, is it not equally possible for other infectious diseases to originate in a similar manner, more particularly glanders—a disease which prevailed to an enormous extent when horses were overcrowded and otherwise badly treated, but is now disappearing under a more enlightened system of management?

It is very true that organisms—micrococci and bacilli—are now found in the bodies of animals during the existence of infectious diseases; but it is quite possible that some of these organisms, or their germs, are always surrounding us, and that only occasionally do they find a proper pabulum in the animal body wherein to develop virulence or infectiveness.
As bearing upon these points, I may relate the history of an outbreak of anthrax, which occurred in this neighbourhood in March 1883, when two horses, five cows, several pigs, and at least two cats had succumbed between Saturday night to Tuesday morning. The post mortem examination revealed splenic apoplexy in all, with well developed bacilli; and an examination of the premises revealed the fact that the water which the animals had been in the habit of drinking was conducted through ordinary drain pipes from a pond, and that over these pipes, which were sunk about eighteen inches in the ground, two large manure heaps had lain a considerable time. They had, however, been removed, but the earth over the drains was saturated with decomposing products, and the water was impure, and, by cultivation in beef tea, and mutton broth, bacilli identical with those found in the blood of dead animals were obtained from it. As anthrax had not been previously known on this farm, I naturally concluded that the Bacillus subtilis, or other organisms—non-infective in ordinary circumstances—had found a congenial soil to develop virulent properties; but it was difficult to account for the great suddenness of the outbreak, as these animals had been drinking no other water for months. There was, however, one fact that threw some light upon what was otherwise mysterious, and this was a very sudden and great change in the weather to extreme cold, with frost and snow, which had rendered the animals predisposed to disease.

A change of water, and the admission of fresh air—of which the animals had been greatly deprived—arrested the outbreak at once, not another case having happened during the twelve months which have elapsed.

Again, several horses in a stud are simultaneously or successively attacked by some epizootic disease, from which some die, the majority recover. One or two overcome the epizootic, but remain debilitated, unthrifty, have a cough, lose condition; in fact, they hang fire, as it is commonly termed—the convalescence being prolonged and most unsatisfactory, one day seemingly doing well, the next day off their feed, shivering, with a staring coat, and a "tucked-up" flank. In the course of a period extending over a week or two, or as many months, a suspicious discharge appears at the nose, the submaxillary lymphatics
become hard and swollen, the Schneiderian membrane assumes an unhealthy aspect—coppery or leaden in hue—and after a time the unmistakable ulceration of glanders is seen in the nostril, fancy buds appear on various parts of the body, and the animals are now unmistakably glandered and farried. If kept in company with other horses, the disease will be communicated to the healthy ones, but if the sufferer be isolated early or destroyed, no further mischief accrues. From bad feeding, overwork, or ill-treatment, the disease termed diabetes insipidus is induced; the majority of the animals recover under proper treatment and a better regime. Some of them remain subject to a return of the polyuria from very trivial causes, and finally it assumes an incurable character, remaining persistent in spite of tonics, good food, proper ventilation, drainage, exercise, &c. As the emaciation increases, fancy buds appear on the surface of the body, suppurate, and discharge an unhealthy pus. By-and-by a discharge issues from the nose, and upon examination the horse is found both glandered and farried; and, as in the other instance mentioned, a centre of contagion is thus formed, from which the disease spreads, if precautionary measures have not been taken.

Glanders from contagion is always made manifest by a discharge from the nose, or by the formation of suppurating abscesses along the course of the lymphatics, without the advent of an interposing disease. Glanders produces glanders—and fancy is but a different manifestation of it—as small-pox produces small-pox, but the specific virus of glanders may be developed by the degradation of tissues consequent upon the ravages of another disease. Thus, in my own experience, in addition to the examples already brought forward, and which may be said to occur not very rarely, glanders has succeeded to a prolonged attack of rheumatism in a weakly made, narrowjointed horse, to castration in the donkey, and it has repeatedly appeared in new and damp stables, amongst horses well cared for and humanely treated in every way, and where contagion or infection were quite out of the question, indeed impossible.

THE CONTAGIUM.

The morbid material which, when once developed in the organism of an animal, possesses the property of causing the
formation of an identical material in the body of another animal, when it is there implanted by direct inoculation or contact, or indirectly through various channels, such as the water the animals drink, or through the medium of the atmosphere—infected—is termed a contagium, morbid poison, materia morbi, specific disease poison, virus, &c.; and is said by Chaudeau to be neither gaseous, fluid, nor volatile, but to consist of minute solid particles.

He has also shown that vaccine fluids, when deprived of these solid particles by filtration, are deprived of all infective properties; and succeeded in proving that vaccine lymph contained two kinds of particles—one much smaller than the other—and that the larger particles are inert, whilst in the more minute is concentrated all the infective properties of the lymph.

Of a germ.—Beale stated that morbid poisons consisted of germs, that the term germ could only be directly applied to a particle that is alive, and that every germ comes from living germinal matter only. But since the discovery—first of Delafond, and then of Davaine—that the blood in splenic fever contained an organism, and the very numerous and important experiments of Pasteur, Chaudeau, Koch, and others, the appellation “germ” has been superseded, and all organisms, whether in the form of spores—Micrococci, rods—Bacilli, or filaments—Mycelia—are recognised under the terms Microbes—small living organisms, Saprophytes—putrid plants, Schizoszymeces—cleaving or splitting fungi, &c.; and it is confidently asserted that the specific particles found in vaccinæ, small-pox, glands—and also the organisms of splenic fever, Chabert’s disease, fowl cholera, pig typhoid, and the other contagious diseases—are living organisms belonging to the vegetable kingdom, having the power of growth and multiplication by cell division, budding, and by the production of cells or spores.

Some organisms, especially those seen in ordinary putrefaction, have the power of motion, and on this account there was for a time a great deal of doubt as to their real nature—animal or vegetable—and it was suggested by Sedillot that they should be called Microbes, or small living organisms; and as they are not destroyed by potash, soda, ammonia, or dilute acids, they are supposed to have a bounding membrane, and that they belong to the vegetable world.
Some microbes are so small, that they approach the limit of visibility, even with the highest microscopic power, and are then distinguished with great difficulty, requiring special staining processes, and sometimes experimental cultivations in suitable fluids.

The diffusion of microbes is very wide, as matters on which they can grow are found almost everywhere,—in dead, moist, or wet organic matter, both vegetable and animal; in water, both stagnant and running; in all putrid or fermenting liquids; and in the surface soil or mould they are found more or less abundantly.

In soils impregnated with liquid manure micrococci are more numerous than rods; but if the soil become very dry, the micrococci disappear, while the rods remain. This is due to the fact that the "resting spores" of bacilli are very tenacious of life. The deeper the earth is dug the microbes become fewer in number, and spring water coming from a great depth contains hardly any.

When putrid liquids or soils dry up, or when decomposing solid substances break up and disintegrate, the bacteria which they may contain pass into the air in immense numbers, and are wafted about as "bacterial clouds." If these be non-pathogenic, no harm may result; but if they possess miasmatic or virulent properties, the atmosphere may thus become the vehicle for the diffusion of disease inducing germs. From this we may conclude that certain epizootics may owe their origin to the diffusion of bacterial clouds.

Seeing, then, that microbes are so universally distributed in air, earth, and water, the question has naturally been raised, whether they may not always have the power of exciting, more or less, grave disturbances in the animal body, as immense numbers are swallowed with the food, and breathed into the lungs at every breath, and all parts of the body exposed to the air come in contact with them. Seeing they are so constant, we must conclude that they cannot generally find in the body the conditions favourable to their development, and that they perish, and are excreted.

Under certain conditions, however, as already pointed out, it is possible that they may find a proper pabulum for their propagation within the body, and be thus converted from non-pathogenic to pathogenic organisms; or poisonous substances
may result from their action upon the blood or tissues similar to that found in putrefying substances—the "sepsin" of Bergmann and Schmiedeberg, and "putrid poison" of Panum.

It was shown by Dr. Carpenter that zymotic poisons (microbes), which have no action on pure blood, will, if that blood contain an appropriate pabulum—accumulation of decomposing matter in the blood, either through its introduction from without (in foul air, impure water, or putrescent food), or through its excessive generation within the body (as by unusual waste of tissue), or by an obstructed elimination of the normal waste (such as results from bad ventilation, or the misuse of alcoholic liquors),—by seizing upon this appropriate pabulum, increase and multiply in it, thus setting up a zymosis in pure blood, just as the growth and multiplication of yeast-cells at the expense of the nitrogenous matter of a wort effects the transformation of sugar into alcohol.

The artificial culture of microbes also proves that, under favourable conditions, their morbid activity may be variously modified. Thus, as microbe of fowl cholera, discovered by Toussaint, when cultivated in chicken broth, proved fatal to fowls inoculated with it; but when the cultivation liquid was exposed to the air—in proper vessels, to prevent putrefaction—for eight or ten months, the virus became altered and so attenuated that it no longer proved fatal, but that fowls became, after one or more inoculations, protected against the unattenuated poison; and, as shown by Pasteur, the activity of the Bacillus anthracis is greatly modified and diminished by cultivation at a temperature of 42° and 43° C.; and animals inoculated with the cultivated bacilli do not die, but are protected against the unattenuated poison.

Even the researches of Koch and his followers do not prove that the bacteria examined by them are constant in their properties, but only that those possessed by a microbe at a given time are retained with some tenacity, even when a certain amount of variation attends its surroundings. The experiments of Naegelli, Davaine, Buchner, and Wernich afford evidence that both the morphological and physiological characters of bacteria are mutable; that changes of the nutrient medium may have some effect on their form and size, on their mode of multiplication, and on their physiological and fermentive properties.

Naegelli says a given bacillus does not invariably produce
bacilli of the same structure, and does not always pass through
the same developmental stages. A bacterium which, under
given conditions, gives rise to a definite fermentation, may lose
this property when cultivated under different conditions, and
Buchner states (1880) that hay bacillus (Bacillus subtilis) can be
transformed into Bacillus anthracis. He says if hay bacilli are
injected into the blood of animals they do not give rise to
anthrax. If, however, they are bred for several generations in
meat extract, and then in the arterial blood of the rabbit, they
acquire noxious properties, and give rise to anthrax in mice after
two to nine days’ incubation; and conversely, if anthrax bacilli
are properly cultivated, they can be transformed into bacilli
whose properties are identical with those of hay bacilli. Without
entering further into the question of the mutability of bacteria,
it is satisfactory to know that the change in the power of their
virulence in cultivation and attenuation, which has already
done much for the prevention of fowl cholera, anthrax, both
splenic fever and Maladie de Chabert, and probably swine plague,
will yet do more in assisting in the suppression of other con-
tagious maladies in which microbes are found to exist.

The virus of contagious diseases is generally contained in its
concentrated and most active form in the discharges which
emanate from that particular part of the body which is most
specially affected; thus vaccine virus is obtained from the vesicle,
&c. But this by no means proves that the whole mass of blood,
and the tissues generally, are not impregnated with the poison;
indeed facts prove the contrary, and the most conclusive one
that can be brought forward is that brought out by the experi-
ment of the late Professor Coleman, who produced glanders in
the ass by transfusing blood into its veins from the carotid
artery of a glandered horse.

The contagium, or virus of a contagious disease, produces its
effects more readily when freshly removed from a diseased
animal; it, however, retains its contagious properties for a very
long time. Glanders virus, vaccine lymph, and cattle plague
poison all act with more or less energy, if kept from undergoing
the process of putrefaction, after a long period has elapsed since
their removal from the diseased animal. Their poisonous pro-
properties are, however, destroyed by heat, it is said, of 120° F.;
but extreme cold seems to have no effect upon them, nor upon
the Bacillus anthracis, which, it has been stated, retains its activity even after boiling; but later experiments have proved that the spores are rendered innocuous, even after two minutes' boiling, as well as by the pressure of twelve atmospheres of oxygen.

The primary effect of a specific disease poison is a deterioration of the blood, and at the same time a multiplication of the poison itself. Some of the most virulent poisons produce their deleterious effects in a very short time, while others have a prolonged period of incubation. For example, splenic fever and death may be induced in a few hours after inoculation, whilst the deleterious effects of the pleuro-pneumonia contagium, or that of rabies, may not be developed for weeks or even months after introduction into the body. Some contagious poisons again seem to affect one class of animals; thus pleuro-pneumonia is peculiar to horned cattle. Epizootic eczema originates in cattle and sheep, but is capable of transmission by direct contact to many other animals, and even to man. Glanders affects the horse and ass, but is communicable to man, dogs, sheep, goats, rabbits, and mice, by inoculation; and rabies, originating in the dog, is capable of transmission to the majority of animals and to man by inoculation. These peculiarities in the action of morbid poisons are mysterious and unaccountable. We must, however, accept them as facts that investigation may some day throw light upon.

The actions of specific disease poisons are compared to that of ordinary poisons, or medicinal remedies given in poisonous doses. They seem to follow certain general laws, the most important of which are—first, that they have all certain definite and specific actions; second, that they all lie latent in the system a certain but varying period of time before those actions are set up; and third, that the phenomena resulting from their action vary, in some degree, according to the dose and to the receptivity of the patient.

The first law, or that of the definite and specific actions of poisons, cannot be doubted; for if it be supposed that agents acting on the human body do not produce their effects according to certain definite laws, we can neither determine the seat nor the course of any disease, nor direct nor judge of the operation of remedies. No one, for instance, has seen castor oil produce tetanus, or colchicum intoxicate the brain, or opium inflame the
spleen. The physician perfectly well knows that the first of
these substances acts on the intestines, the second on the liga-
ments, and the third on the nervous system generally. The
action of poisons, therefore, is not accidental, but determined by
certain definite laws.

The action of poisons, though definite, is variously limited.
Some poisons, for instance, act on one membrane, or on one
organ, or on one system of organs; while other poisons extend
their action over two or more membranes, or organs, or systems
of organs, or even over the whole animal frame. We have
examples in aloes and jalap of substances that act mainly upon
the mucous membrane of the alimentary canal. In digitalis we
have an instance of a medicine that principally acts on the heart,
greatly reducing or even stopping its action; while strychnine
is an example of a medicine acting on the parts supplied by the
spinal cord, producing powerful and sometimes fatal tetanic
action of every voluntary muscle in the body.

It is seldom, however, that the action of poisons is limited
to one membrane, or organ, or system of organs. The greater
number of these noxious agents more usually act on two or
more membranes, or organs, or systems of organs. Elaterium,
for instance, acts on the mucous membrane of the intestinal
canal, and on the kidneys. Tobacco nauseates the stomach,
intoxicates the brain, and affects the action of the heart.
Antimony has an equally extensive range; it induces cutaneous
perspiration, acts cathartically and emetically, and in large doses
appears to cause gangrene of the lungs. Alcohol and opium are
examples of substances acting still more generally, affecting not
only the action or secretion of every organ or tissue of the body,
but even in some instances altering their structure. Thus alcohol,
in its most limited action, has been shown to cause structural
disease of the liver, of the stomach, and of the coats of the
arteries. From the circumstance of these substances acting not
only generally, but inducing local lesion, they resemble in their
effects those of many morbid poisons, as that of typhus fever, of
scarlet fever, of small-pox, or of syphilis.

The second important law of poisons is, that they lie latent in
the system for a period of time which varies in different individu-
als, before they set up their specific actions. Rhubarb, for
instance, produces no immediate result, but lies dormant in the
system six or eight hours before its action is sensible on the bowels; opium, in the usual dose, is generally thirty minutes before it subdues the brain. The convulsions from strychnine do not follow till twenty minutes after its administration; and perhaps every substance, except hydrocyanic acid, has a greater or less sensible period of latency.

When a medicine acts on more parts than one, a considerable space of time may elapse after it has affected one organ before it affects another: thus digitalis frequently occasions emesis before it acts on the heart, and the action of mercury on the bowels is frequently sensible for many weeks before the gums and salivary glands are affected. The doctrine of the latency of poisons is indeed so generally admitted, that the actual period has been a point on which the condemnation or acquittal of a prisoner tried for murder has turned in our courts of justice, when certain poisons have been supposed to have been given.

The third great law of poisons is, that their effects are modified by the dose, the temperament, and the existing state of the constitution, mentally and bodily, of the recipient. The effect of the dose in modifying the pathological phenomena of disease may be exemplified in the actions of oxalic acid and of arsenic. The specific action of oxalic acid is to inflame the mucous membrane of the stomach; but to insure this effect the dose must be limited, so that this poison may lie in the system many hours. On the contrary, if the dose be excessive, and rapidly absorbed, the poison so disorders all the functions of the three great nervous centres that life is destroyed in a few minutes. Arsenic, likewise, is a poison which inflames and ulcerates the mucous membrane of the alimentary canal, but it requires some hours to set up its specific actions; for, when the dose is large, it, in like manner, destroys by general irritation, and before traces of morbid change of structure can be appreciated after death. It follows from this law that the larger the dose or the greater the intensity of the poison, the more rapid its action, and the less the probability of finding any trace of specific lesion induced by it.

In the same manner the action of specific disease poisons is also limited, some affecting one membrane, or one organ, or one system of organs. Morbid poisons have also their periods of latency, during which they seem to lie in the system before exercising their specific action. This period of incubation is
indefinite in some diseases; whilst in others, such as rinderpest, it is definite, producing its specific action in seven or eight days. In addition to its action upon a membrane, or organ, or upon the whole body, a specific virus has, besides poisonous effects upon the blood, the power of causing certain physical alterations in that fluid. Andral has found that a specific cause has a tendency to destroy or reduce the quantity of fibrin in the blood, and that this defect of fibrin is the cause of the great tendency to haemorrhage, and to that stasis or congestion so remarkable in typhus fever, scarlatina, and other specific diseases.

The facts and arguments which have been adduced prove that morbid poisons act in all instances not capriciously, but according to certain definite and specific laws, modified by the influence of climate, temperament, or the magnitude of the dose; also, that they mingle with the blood, with which they continue in latent combination a certain but varying period of time; and likewise that many of them are capable of co-existing together in the same system. A knowledge of these facts is necessary to the proper understanding of this class of diseases, and it is hoped that by their application many of the difficulties which have hitherto obscured the doctrines of fever, of syphilis, of hydrophobia, and of many other diseases incident to this class of morbid poisons, may be removed, and that this portion of medical science may be placed on a surer foundation, if not on a permanent basis.

The experiments of Panum of Copenhagen in 1856, with an artificially prepared septic fluid, are very interesting, and to some extent bear upon the question.

Panum's earlier researches were directed to the participation of the minutest living forms in the production of the symptoms of septicæmia. "Is it the case," he inquired, "that the microscopic organisms which are always in putrid liquids stand in such relation with the group of symptoms which are observed when such liquids find their way into the circulating blood or into the tissues, that these symptoms cannot present themselves if the infecting liquid is either deprived of its organisms, or subjected to some process by which their vitality is destroyed?" This question Panum answered in the negative.

Having first carefully studied the pathological process itself,
so as to determine its characteristics, and to be able to recognise them with certainty, and having ascertained that they were the constant results of the introduction into the circulation of certain kinds of putrid infusions, he set to work to devise a method by which the influence of the particular factor of which the potency was in question, namely, the living organisms contained in such infusions, could be separately tested. With this view, the following plan of experiment was adopted. An infusion of flesh having been allowed to stand in a warm room for two or three weeks, was carefully filtered, then boiled for several hours, and finally evaporated to dryness on a vapor bath. The thoroughly dry residue was then digested, first with cold and then with boiling alcohol. After the alcoholic extract had been removed and set aside, the insoluble residue was extracted, first with cold and then with boiling distilled water, and filtered hot. The aqueous extract, which obviously contained exclusively matter insoluble in absolute alcohol, when injected into the circulation of dogs, in a number of instances produced all the symptoms of septic infection, namely:—In about half an hour after the injection the animal began to be unwell. About fifteen minutes later there were horripilation along the back, and slight twitchings of the muscles of the extremities. Soon after, retchings commenced, andropy saliva was copiously discharged from the mouth. Then followed repeated efforts to discharge feces, the evacuations being at first natural, then accompanied with much mucus. At the end of two hours the pulse was accelerated, the pupils strongly dilated, and the depression was so great that the animal was unable to stand, the alvine symptoms remaining as before. After the fourth hour the animal began to improve. The following morning it was willing to take food, and was rapidly recovering. It was then killed by pithing, and then immediately dissected. The only pathological appearances observed were those referable to the intestine. The mucous membrane of the duodenum exhibited tracts of congestive hyperaemia, and it was so much swollen that the patches of agminate glands appeared as insular depressions.
CHAPTER XV.

CONTAGIOUS DISEASES.

CATTLE PLAGUE.

Synonyms.—Rinderpest (G.); Typhus boum contagiousus ¹ (L.); Pièvre pestilentiel du gros bétail (F).

Definition.—A specific, malignant, and contagious fever, indigenous to the Asiatic steppes of Russia, also Hindostan, Persia, China, Burmah, Cochin-China, Thibet, Ceylon, &c., never occurring in this country but as the result of direct or indirect communication between imported cattle (which have been exposed to the contagium) and those of our own shores. It is unknown in America and Australia. The disease has a period of incubation, varying from four to eight days, at the end of which time its local manifestations are generally developed. It runs a definite course, and usually terminates fatally; but where recovery takes place, the animal is rendered unsusceptible to another attack.

It is essentially a disease of the bovine family (the ox, auroch, and zebu), but it may be communicated to the sheep, goat, deer, camel, giraffe, antelope, gazelle, and even the peccary.

It is said that an accidental inoculation of the human skin with the juices of an animal which had died of rinderpest has caused the formation of a pustule similar to that of variola vaccina.—(See Appendix to the Third Report of the Commissioners appointed to inquire into the origin, nature, &c. of the Cattle Plague, page 79.)

¹ The word contagious was introduced into medicine by Vegetius, and is now recognised as a generic term.
PATHOLOGY AND SYMPTOMS.

The specific poison or contagium absorbed into the blood gives rise to primary fever. This fever, as indicated by a rise in the temperature, precedes all other symptoms, and occurs in a period ranging from thirty-six to forty-eight hours after an animal has been inoculated. The elevation of temperature varies to some extent. As an average of the normal temperature of the healthy ox during different periods of the day, 101° may be accepted. During rumination it may be as high as 103°, and may then fall to 100°, or even lower. Taking 101° as the standard average, it has been found that the temperature may rise 2°, or even 3°, in from thirty-six to forty-eight hours after inoculation, namely, to 103° or 104°; this elevation of temperature occurring when the animal appears to be otherwise perfectly well. From this we learn that the true period of incubation—latency—is very short indeed, and that although there are no symptoms visible to the ordinary observer, the disease has actual existence.

Two days after the perceptible rise of temperature has begun, an eruption on, and a peculiar appearance and condition of the mucous membrane of the mouth is seen, having some resemblance at first sight to the appearance of that found in the foot-and-mouth disease. In some rare instances, however, this characteristic symptom has been absent. I have seen it in every case of the plague but one which has fallen under my own observation, and usually veterinary surgeons have been able to diagnose the disease by its presence. Almost simultaneously with this appearance of the mouth, the mucous membrane of the vagina of the cow becomes peculiarly altered. One or other of these signs is rarely absent; so that when they are taken in connection with the elevation of the temperature, the diagnosis of the disease can be made with certainty.

On the day following the eruption in the mouth, or about seventy-two hours after the first elevation of temperature, the animal may be observed to be a little ill, to have less appetite than usual, and to ruminate irregularly. Even at this time, however, the pulse may be unaltered. On the following day, the fourth from the first rise of temperature, the animal, for the first time, shows marked symptoms of illness; and this period, which may be one hundred and ten hours after the real
commencement, is usually considered by superficial observers as the beginning of the disease. The seriousness of the oversight is obvious, on account of the great importance of the earliest possible separation, isolation, or more particularly the slaughter of the diseased animal, and of all cattle with which it may have been in contact.

After the fourth day is over, the constitution is thoroughly invaded. Then ensue the urgent symptoms—the drooping head, hanging ears, distressed look, rigors and twitchings of the superficial muscles, failing pulse, oppressed breathing, fetid breath, and the discharge from the eyes, nose, and mouth.

During the sixth day there occurs a great diminution of the contractile force of the heart and voluntary muscles, the pulse becomes feeble and thready, the respiratory movements are modified, and the animal sometimes shows such weakness in the limbs that it has been thought that some special affection of the spinal nerves must exist. The temperature now rapidly falls, and signs of a great diminution in the normal chemical changes in the body present themselves.

Death usually occurs on the seventh day from the first perceptible elevation of temperature.

Although this is given as the typical course of the disease, there are great deviations from it, as some animals live a longer, many a much shorter time, and the severity and sequence of the symptoms vary considerably.

The disease is induced by a micro-organism, which causes in the first place a morbid state of the blood; for, coincident with the first elevation of temperature, and, of course, long before there is the least outward appearance of ill-health, the blood of an animal which has taken the disease contains an agent which can produce the plague in another animal. In other words, the earliest fact which can be made out after infection is, that the blood contains the poison of the disease, so that serum obtained from it will give the disease by inoculation. This fact was ascertained by Dr. Sanderson, and is a most important discovery, and, according to the Commissioners, "is pregnant with consequences in medical doctrine;" for though (they say) the existence of a similar fact has long been suspected in several human diseases, it has never been proved in any. When the Commissioners made this assertion they were evidently ignorant of the
fact that Coleman had demonstrated the presence of the glanders poison in the blood, and had induced glanders by transfusion.

The morbid poison is also contained in the discharges from the mouth, eyes, intestinal canal, &c. of an animal ill from the cattle plague, and a small quantity of the mucus from the nose, eyes, or mouth, when placed in the blood of a healthy animal, increases so fast, that in less than forty-eight hours, perhaps in a shorter time, the whole mass of blood, weighing many pounds, is infected, and a very small particle of that blood contains enough poison to give the disease to another animal. This at once accounts for the rapid spread of the cattle plague. The agent is multiplied to a large amount in a very short space of time. How soon after the poison is put into the blood the animal becomes capable of giving the disease by natural infection to other animals is not determined, but in all probability long before it is, as it were, impregnated with the poison; for it stands to reason that all parts of the body, out of which secretions are poured, must contain more or less morbid material when that material is contained in the whole mass of blood.

It has not been determined to what length of time the blood and textures retain the power of propagating the disease. Professor Jessen of Dorpat, however, says that the mucous discharges, carefully protected, occasionally retain their power of causing the disease by inoculation for no less than eleven months.

The morbid poison can be diffused and the disease communicated by the air for a distance of about five hundred yards; but beyond this distance it is said the poison remains ineptive. It is also conveyed by flies, which, after resting on a sick animal, or its offal, fly about and alight on healthy animals.

The fever, as shown by the elevation of the temperature, begins when the poison has infected the whole mass of blood, or within from about forty to sixty hours after its first entrance into the system. Coincident with the elevation of temperature, the chemical changes in the body are augmented, and, according to Dr. Marcet, one of the products of degradation of tissue—the urea—is largely increased. Soon afterwards the blood is otherwise altered, the amount of fibrin largely increased, the amount of water lessened, and the physical condition of the albumen altered; and, according to Dr. Beale, the proportion of soluble substances is also largely increased.
About the third or fourth day local congestions are to be seen on the skin and visible mucous membranes, varying in intensity and in size. Stagnation takes place in the small capillaries of many parts of the body, the blood in which becomes coagulated. A great increase of granular matter is found to occur both within and without the vessels of the congested parts. The capillaries become greatly enlarged, and the spaces between them lessened or obliterated. At the same time considerable nutritive alterations take place in the mucous membrane and skin, leading to very rapid and imperfect growth of many of the cellular elements, and followed by rapid disintegration and detachment in the form of discharges. As that portion of the mucous membrane which is most essential for digestion is most affected, the appetite soon fails, rumination ceases, and large accumulations of undigested food are met with in the first stomach. In many cases the villi of the small intestines are so destroyed, that even if food were taken it would scarcely be absorbed in sufficient quantity to maintain life, and hence the rapid exhaustion, failure of the heart’s action, depression of the animal heat, and general sinking of the powers. In some cases, when the process is more superficial, the membrane rapidly recovers its healthy condition; and it is curious to find that one affected part may be healing while another is just beginning to suffer.

When, as sometimes happens, the mucous membrane most affected by the congestion is that of the bronchi, the phenomena are not less severe; indeed, the disease is sometimes even more rapidly fatal. A slight cough is soon followed by accelerated breathing, which rapidly increases; and, according to Drs. Sanderson and Bristowe, the difficulty in breathing becomes so great, that some of the pulmonary vesicles are broken, and emphysema, not only of the lungs, but of the subcutaneous tissues of the neck and back, is thus induced. I cannot, however, endorse this, being of opinion that both the pulmonary and subcutaneous emphysema are due to the formation of gases in the areoles of the connective tissue.

Dr. Beale, after microscopically examining the discharges from the mucous membranes with the highest magnifying power, namely, the \( \frac{1}{4} \)th of an inch objective glass, arrived at the conclusion that the abundant granular matter which he
thus discovered consisted of living particles—germinal matter—that they constituted the morbid poison, and that the various local congestions were due to the abundance of these particles, blocking up the minute capillaries. This view, however, has not been generally accepted. "Very possibly the granular matter may contain the morbid poison, or it may exist in a granular condition too minute to be discovered by an instrument that magnifies 2800 diameters; that is to say, it may exist in a definite form still smaller than \( \frac{1}{1000} \) of an inch; but inasmuch as the granular material discovered by Dr. Beale has no definite form which distinguishes it from material discoverable in other conditions of the animal body, it cannot be said that the virus has as yet been discovered. Again, chemistry has found no complex albuminoid substance in a state of rapid chemical change capable of communicating its own action to the albumen of the serum of the blood or the textures of cattle."—(Dr. Sanderson.) Nor can the more definite experiments of Chauveau be said to prove more than that the morbid material of this and other contagious diseases is contained in the cellular elements of animal discharges; in fact, that the cells themselves are merely the vehicles in which the virus is contained.

With reference to the true nature of the cattle plague, and its identity with or resemblance to various human maladies, many theories have been advanced by writers upon the disease. Some have considered it to be the precise counterpart of typhoid or enteric fever, and this view has been held by the German pathologists for a considerable period, and was undoubtedly the view held by most veterinary surgeons who had the opportunity of witnessing it in this country. Dr. Murchison, however, successfully combats this view, and very lucidly points out its error. He says, "Human enteric fever is characterised by definite and easily recognised anatomical lesions; and for my own part I have been unable to discover any analogy whatever with them in those of rinderpest. The alterations in Peyer's patches in the latter disease are clearly the result of the general inflammation of the mucous membrane, and tend to obliterate the glands, instead of rendering them more prominent. Their resemblance to the lesions of enteric fever is much less than that of the condition of the corresponding glands in cases of cholera, smallpox, scarlatina, pyaemia, and other blood diseases. It is probable
CATTLE PLAGUE

that the diminution in the size of Peyer's patches in rinderpest, as compared with the glands in a healthy ox, may be due in part to the length of time that has elapsed since digestion has been arrested, as it is well known that these glands are larger and more developed during the digestive process than during fasting. But, whatever be the cause, nothing can be greater than the contrast between the appearance of these glands on the tenth day of rinderpest and on the corresponding day of human enteric fever. In the former case the glands have almost, if not entirely, disappeared; in the latter they are enormously prominent, owing to abnormal deposit in and around the glandules." Dr. Murchison quotes the writings of several observers, who agree that the intestinal glands are not enlarged; on the contrary, that they are usually diminished in size, often covered over with a layer of discoloured and softened mucous membrane. "Peyer's glands," says Professor Simonds, in his Report on the Cattle Plague, published in the Royal Agricultural Society's Journal, 1857, "are not invariably diseased; but like other follicular openings of the digestive canal, they are often covered with layers of lymph, beneath which ulceration is occasionally observed, but more frequently the surface is healthy, although tinged with blood." After further comparing cattle plague with typhus, influenza, dysentery, erysipelas, scarlatina, and variola, Dr. Murchison concludes that cattle plague has no resemblance to typhoid fever, typhus, scarlatina, erysipelas, influenza, or dysentery, but that it resembles small-pox. He says—

"1. Small-pox is the only acute contagious exanthem in man that assumes a pustular form. The eruption in rinderpest is also pustular. Any difference between the two eruptions may readily be accounted for by the differences in the skin of man and cattle. In both cases the eruption extends from the skin to the interior of the mouth and nostrils; and in both the pustules are often interspersed with petechiae. Moreover, in certain cases of rinderpest the eruption on the udder assumes the form of large flattened vesicles, indistinguishable from those of ordinary cow-pox.

"2. The other prominent symptoms of rinderpest are also those of small-pox—viz., pyrexia, lumbar pain, running from the nostrils, alvine flux, albuminuria, and haematuria, and the 'typhoid state.'
“3. The anatomical lesions of the two diseases are identical—viz., inflammation of the mucous membrane of the air passages and digestive canal, dark-coloured blood, ecchymosis, and a pustular eruption with petechia on the skin.

“4. In both diseases a peculiar offensive odour is exhaled from the body both before and after death.

“5. In both the duration of the pyrexial stage is about seven or eight days.

“6. The two diseases resemble one another in their extreme contagiousness, and in the facility with which the poison is transmitted by fomites.

“7. Both diseases can be propagated by inoculation. This can be said with certainty of no other human malady than small-pox.

“8. In both diseases there is a period of incubation, which is shorter when the poison has been introduced by inoculation than when it is received by infection.”

Dr. Murchison gives four more reasons, which I need not quote. The promulgation of his theory during the prevalence of the plague in 1866 led to the belief that vaccination would prove a preventive, and immediately cattle all over the country were vaccinated, very much to the benefit of the vaccinators but not of the cattle, for it proved a total failure; except, indeed, that it confirmed the view that rinderpest was not variola, but a disease having some resemblance to cholera, scarlatina, and to diphtheria, at the same time having characteristics of its own which separate it from all other diseases, and prove it to be an incurable and highly contagious malady, very properly denominated “the cattle plague.”

To my mind, the greatest point of resemblance, mentioned by Dr. Murchison, which cattle plague bears to small-pox, is the eruption; but if rinderpest were at all associated with small-pox, one would suppose that the pustular eruption would scarcely ever be absent, as it is a characteristic symptom of small-pox; but so far as my experience goes, an eruption on the skin is scarcely ever present in the cattle plague. I must, however, speak within my own experience, and with all due deference to the observations of others: the disease as manifested in Yorkshire and Lancashire, where I had the opportunity of seeing it, seldom presented any cutaneous eruption at all.

Mr. John Gamgee, in his work on the Cattle Plague, very
successfully controverts the conclusions of Dr. Murchison, and if the reader is desirous of further information he may consult that work with great advantage.

In addition to the general symptoms of cattle plague which are embraced in the foregoing observations, the more particularly visible signs are worthy of notice; and these are shivering, muscular twitchings, restlessness, often a husky cough, yawning, sometimes great dulness, with drooping of the ears, sometimes excitement approaching to delirium, appetite at first capricious, but soon becoming entirely lost, suspension of rumination, and secretion of milk arrested. The latter symptom was one of great significance amongst cattle owners during the prevalence of the plague, the arrestation being much more sudden and complete than in any other disease. The shiverings and muscular twitchings are not always observable in the earlier stages of the disease, but often seem to usher in the second stage, when the symptoms present a more aggravated character. The animal now incessantly grinds its teeth, arches the back, and draws its legs together, moans, and otherwise shows signs of much uneasiness. The eyes, mouth, and nose are at first dry, hot, and red; the legs and ears are generally cold. At first the bowels are constipated, but this condition is succeeded by violent purging, and the dry condition of the mouth, nose, and eyes is followed by a discharge of a glairy watery character, soon assuming an opaque or turbid nature, which is very typical of the disease. The respiratory movements are generally but not always accelerated; the inspiratory movement is quickened, whilst the expiratory is rather prolonged, and accompanied by a low moan.

The colour of the visible mucous membranes becomes peculiarly altered. In some cases they present a characteristic salmon-red colour over their whole extent, with deep crimson-red patches interspersed here and there.

Dr. Sanderson, in his Report to the Commissioners, and Professor Gamgee, in his book on the Cattle Plague, quote the observations of Jessen and other Continental veterinarians. Jessen says—"The appearances observed by me on the mucous membrane of the mouth, both in the natural and inoculated disease, are as follows:—' In some cases, small round nodules, seldom larger than a millet seed, are observed, which are still covered with epithelium, through which a yellowish or yellowish-
grey material can be distinguished. A few hours later (sometimes not till twenty-four hours) the epithelium gives way, and the contents become visible; hence results a superficial lesion, which, after the removal of the material lying upon it, is scarcely recognisable; it heals in a few days, leaving no cicatrix. In other cases these nodules become confluent, and then give rise to an excavated ulcer of considerable extent, with irregular margins, which, however, usually heals quickly, leaving no cicatrix. In another form of the affection the epithelium is raised in the form of small vesicles, which contain either a clear or slightly turbid fluid, and leave behind shallow, round excavations, with smooth edges."

Dr. Braunell of Dorpat, who has made very extensive observations on the anatomy and microscopy of the disease, says that the buccal mucous membrane is usually reddened in patches of greater or less extent; these patches being in some places merely deprived of epithelium, in others covered with layers, varying in size from that of a lentil to that of a fourpenny piece. These layers are of a yellow or greyish colour, and of irregular form; they project from one to two lines above the surface of the reddened mucous membrane, and are so soft that they can be readily stripped off with the tip of the finger. The mucous membrane beneath is more or less reddened by congestion of the capillaries and haemorrhage, and in some cases broken down in its texture; usually, however, it is entire. Similar alterations are found at the margins of the lips and nose. In addition to these changes, roundish depressions about as large as a hemp seed, their bases covered with a yellowish material, were observed in the mucous membrane of the lips, and sometimes along with them greyish nodules, which might on superficial examination be easily mistaken for vesicles or pustules. On pressing these, a yellowish, semi-fluid mass could be squeezed out, leaving behind one of the depressions or pits above described. These were the appearances seen in animals suffering from the disease naturally contracted. Those seen in inoculated animals did not materially differ. On the third or fourth day after inoculation there was redness of the gum around the incisor teeth, and, more rarely, injection of the mucous membrane of the lower lip. At these spots the membrane was covered with a yellowish-white material, which could easily be stripped off.

leaving small roundish pits. About the same period of the
disease, nodules similar to those above described were observed
on the lower lip.

"As the disease advances the animal becomes exceedingly
restless, lying down and rising again, and otherwise denoting
abdominal and colicky pains. Whilst lying down, the head is
generally turned upon the upper flank. The voluntary muscles
are, in most cases, affected with clonic spasm, and constant
twitchings of them occur, more particularly about the neck,
shoulders, and hind quarters. Diarrhoea sets in, and the animal
becomes in some cases very thirsty; in others, there is loathing
both of food and drink. The intestinal discharges, at first black,
become of a pale greenish-brown colour, and are very foetid; and
as these are voided they cause much straining (tenesmus) by irri-
tating the rectum. The urine is rather scanty, dark coloured,
and sometimes albuminous." The pulse now becomes much
accelerated and very feeble—as high as 120 to 140 per minute;
the surface of the body deathly cold; the general weakness
increases rapidly, the animal standing with difficulty, and
lying most of the time; the cough is weak and soft; the sub-
cutaneous areolar tissue becomes, but not invariably, emphy-
sematus; the buccal membrane and gums are covered with
masses of bran-like epithelial scales; the angles of the mouth
ulcerated; the vagina of the cow and the preputial orifice of
the male present a dark, deep redness. The animal is drowsy
and unconscious; the breathing is performed with a spasmodic
jerk; the alæ of the nostrils spasmodically open and shut; and as
death approaches, the mucous membranes acquire a leaden hue;
whilst dark coloured spots of erosion and ecchymosis stud their
surfaces. Tympanitis sets in, and the discharges from the
bowels are involuntarily excreted, whilst muscular twitchings
denote the approach of death.

Some cases of cattle plague recover, and in these cases it is
observed that the skin over the neck, withers, &c. becomes
covered with a yellowish sebaceous secretion, but there are no
vesicles or pustules. In some of the fatal cases it is said that
there is an eruption: the disease in this respect must, however,
differ in different localities.

I have seen recovery take place where subcutaneous em-
physema was present over the greater part of the body.
Now and then a relapse takes place after signs of improvement have become established, and in some instances animals apparently quite convalescent commence to purge, and to sink from intestinal and other complications.

Mr. Gamgee says that the disease is periodical in its manifestations: "Improvement in the morning; exacerbations at night; a distinct subdivision of an attack into stages, and from the date of the crisis either sudden aggravation or gradual abatement of alarming symptoms". This periodicity may exist to some extent; it is, however, so slight as to escape ordinary observation. Indeed, in many instances I have observed that the symptoms were quite as bad in the morning as in the evening.

The mortality in Great Britain is always very great. Amongst Russian cattle mild cases of the disease are not of uncommon occurrence, the animals passing through the disease presenting but slight symptoms of it. But even in Russia from 80 to 90 per cent. is reckoned the usual mortality, and under the most favourable circumstances 53 and 56 per cent. have been witnessed.

Although the disease is so highly contagious, it is found that some cattle resist its influence, remaining healthy whilst surrounded with the plague; but it is also no less remarkable that an animal thus exposed to the contagium will, whilst resisting the malady itself, convey the disease to other cattle, the morbid material being lodged about its body.

The post mortem appearances of cattle plague vary in different stages.

In the first stage there is congestion of the mucous membranes of the mouth, larynx, pharynx, and particularly of the fourth stomach near its pyloric end, the small intestines are marked with streaks and patches of red, and the follicles are uniformly reddened.

The surface of the mucous membrane is covered with a viscid, tenacious, and bloody secretion; is denuded of its epithelium, whilst the submucous tissue is charged with a turbid semi-fluid exudate. The condition of the first two stomachs calls for no special remarks. Sometimes the rumen presents patches of congestion on its mucous surface, approaching in tint the colour of port wine, and in a very small number of cases sloughing of the membrane has been observed.

The condition of the third stomach has been supposed to give
origin to the disease; hence the Germans have called it Lösen-
dürre—impaction of the third stomach. The late Professor Dick
for a long time held out that the disease was neither more nor
less than this impaction of the omasum, that it was consequently
a non-contagious disease, and that if by the timely administra-
tion of purgatives the stomach could be unloaded, the animal
would be restored to a healthy condition. And Dr. Bristowe, in
his report to the Commissioners, says, "The contents of the
omasum are almost invariably preternaturally dry and caked,
and as they are at the same time moulded accurately to the
highly papillary surface of the folds of this stomach, it is probably
due to the concurrence of these two conditions that the epithelial
covering of the folds (when, as often occurs, its normal attach-
ments are loosened) becomes so frequently in this disease removed
with the food." Now, I am of opinion that the majority of
observers have fallen into some degree of error as to the abnormal
state of the contents of this viscus; and have concluded that,
because the food is found dry and moulded to the leaves, the
condition is unnatural, whereas in reality (as may be confirmed
any day by calling at a slaughter-house where healthy cattle
are slaughtered) the condition of the contents of the omasum
is almost invariably firm, the viscus having the appearance of
being impacted.

In some instances the leaves of the omasum are quite healthy;
sometimes they are slightly reddened, the vessels which radiate
from their attached border being more or less injected, and
sloughing may occur in patches.

The fourth or true digestive stomach—the abomasum.—The
contents of this stomach are nearly always fluid, and sometimes
mixed with blood, and the specific lesions of the disease are
intensely marked in this organ. Its mucous membrane is not
only intensely red and covered with adhesive mucus, but is
studded with numerous superficial erosions, like those which are
so common in the ordinary catarrhal inflammation of the human
stomach.—(Murchison.) The mucous membrane is easily re-
moved from the submucous tissues, and the gastric glands are
filled with granular epithelium and with blood. "In addition
to the general redness," says Dr. Murchison, "which is most
intense in the pyloric region, the mucous membrane at this part
often presents circular or irregular patches of a claret colour,

² See Plate II.
the rim of the glottis is considerably swollen, and the tonsils much enlarged. Emphysema of the lungs is very commonly met with, and is a condition which causes great distress to the animal prior to its death. The remarks of Dr. Sanderson upon this point are very interesting. He says, "During the first stages of the disease respiration is performed in a perfectly natural manner, but about the fifth day irregularities begin to be observable. From time to time the rhythmical movements of the chest are interrupted, and expiration is accompanied by an audible moan. On the sixth day (that is, in fatal cases, the day before death) the breathing usually assumes a character which is so remarkable that if once observed it cannot be forgotten. The chest dilates suddenly, but apparently with considerable effort, in consequence of, as I believe, the unnatural permanent expansion of the lungs due to obstructed expiration. This inspiratory movement is immediately followed by closure of the glottis, the expiratory muscles being at the same time thrown into violent action, much in the same way as they are in the act of rumination. The closure of the glottis is always attended with a sound (such as might be produced by the sudden closure of a soft leather valve) so loud that it can be heard at a considerable distance. This sound coincides with the resisted expulsive effort, which is often so strong as to throw the whole body of the animal into oscillation. The chink of the glottis is continuously closed for one and a half to two and a half seconds, the chest remaining expanded and motionless. At the end of this period the air shut up in the thoracic cavity is expelled with a peculiar grunting noise, which is quite as characteristic as the valvular sound already described. It is immediately followed by a renewed inspiratory effort." Dr. Sanderson says that this peculiarity of movement is the cause of the interlobular emphysema. He says, "The pause, instead of occurring between each expiration and the succeeding inspiration—that is, when the breathing apparatus is in a state of relaxation—occurs when the chest is expanded, or, more accurately speaking, in the middle of the expiratory act; for, inasmuch as the expulsion of air from the chest commences immediately after the chest is filled, a considerable quantity escapes before the glottis has had time to close. At the moment that closure takes place the air confined in the chest is strongly compressed by the action of the
expiratory muscles, and in this way gives rise to the interlobular emphysema, which is so commonly observed in cattle plague."

I feel compelled to differ from Dr. Sanderson on this point; my own observations leading me to the conclusion that the emphysematous condition of the lungs is due to the generation of gases in the interlobular lung tissue, and that the peculiarity of the breathing results from, and is not the cause of, the emphysema.

The other organs of the body do not present many post mortem signs which may be called peculiar to the disease. The heart is often covered, both externally and internally, with petechial spots.—(See Plate V.) The liver is sometimes pale, sometimes dark; the gall bladder is usually full of bile, and sometimes covered with aphthous patches.—(See Plate IV.) The spleen is usually healthy, a circumstance of great interest, says Professor Gamgee, when taken in connection with the condition of this organ in the typhus and typhoid fevers of man.

The lining membrane of the vagina and uterus, like the mucous membranes of other parts of the body, are deeply tinged with various degrees of redness and purple, and their epithelium is in a softened and semi-detached condition.

The skins of animals suffering from cattle plague present a variety of appearances, such as crusts, eruptions, pustules, and elevations. In inoculated animals dermic alterations are said to be pretty constant, but, as already indicated, they were absent in those cases which fell under my notice whilst the disease was raging in Yorkshire. They were, however, carefully looked for in every post mortem examination which I made. Dr. Sanderson says that "they may be described generally as consisting in the first place of incrustation of material exuded in a soft or semi-solid state from the glandular follicles of the skin; and, secondly, of pathological changes in the superficial structures of the skin, which, without taking anything for granted as to their nature, may be designated by the term eruption."

CHAPTER XVI.

CONTAGIOUS DISEASES—continued.

CATTLE PLAGUE—continued.

From the observations of Dr. A. Gamgee, Dr. Marcet, and others, it appears that the blood of an animal affected with the plague is usually of a darker colour than healthy blood, that it coagulates more slowly and very firmly, and that after standing a long time but a very small quantity of serum separates. It contains more fibrin and extractive matters than healthy blood. The latter contains 3.4 of fibrin in 1000 parts, whilst the former contains 4.5 in 1000 parts.—(Dr. MARCET.) Dr. Gamgee's researches lead him to conclude—

1st. That the amount of serum is remarkably diminished, and therefore the total solid matters of the serum in 1000 parts of blood are noticed to be much below the healthy standard.

2d. The amount of fibrin is increased, especially in the severe cases.

3d. The amount of corpuscles is decidedly increased.

That the quantity of serum is decreased cannot be wondered at, when we take into consideration the diarrhoea which is so symptomatic of the later stages of the plague; and, as Dr. Gamgee justly concludes, the intestinal discharges probably contain a large amount of albumen. The increase of the corpuscles can only be relative, in consequence of the decrease of the serum, their absolute amount remaining stationary.

THE MILK.

The changes in the milk appear to be as follows:—

1st. The amount of sugar of milk is remarkably diminished.
2d. The amount of butter is (except perhaps at the commencement) enormously increased.
3d. The salts are slightly increased.
4th. The casein appears to be generally increased.—(Dr. A. Gamgee)

THE URINE.

The urine contains more urea than in health, and a study of the following table will at once give the reader an idea of the condition of the urine both in health and in rinderpest:—

(Dr. Marchet.)

Died on 10th December.
SHORT HISTORY OF THE CATTLE PLAGUE IN BRITAIN.

In 1348-9 a plague or murrain broke out amongst the cattle in England. It appeared just after the black death had destroyed thousands of human beings, and seemed to be similar to the cattle plague. Mr. Fleming, in his work on the History of Animal Plagues, gives much interesting information upon the subject. The importance of the "stamping out" system seemed to be comprehended in those days. The diseased cattle were slaughtered, and infected herds were as much as possible separated from those which were sound, while the herdsmen who attended the former were not allowed to come in contact with the latter. In 1480 another outbreak of disease (murrain) took place, and committed great devastation. There are, however, no accurate accounts of the symptoms, &c. of these diseases. It is therefore impossible for any one to state that they were identical with cattle plague; but there is every reason to believe that the outbreak occurring in 1715, which renewed its attack in 1745, and remained here till 1757, was the same as the plague of 1865.

The plague of 1745 was brought to this country by two white calves imported from Holland by a farmer living near Poplar. Another account states that it was brought here by a tanner, who bought a parcel of distempered hides at Zealand. It appears these hides had been forbidden to be sold there, and were ordered to be destroyed. Both accounts state that the disease broke out near London, and that it continued to ravage the herds for twelve years, and was only suppressed by vigorous measures being taken by local and other authorities.

It is curious to note that the local authorities of those days were very similar to those of the present time. In the First Report of the Cattle Plague Commissioners, 1865, it is stated that in 1747 various orders were issued stopping local fairs, and empowering local authorities to do so when they found it expedient.

"The plague, in consequence of these orders, was extingushi...
it can very truly be said that some of the local authorities tried to suppress these diseases, and would have succeeded, had it not been for the laxity of other local authorities.

The origin of the outbreak of 1865 is, according to Professors Simonds, Gamgee, and others, as follows:—"Early in 1865 an Englishman, James Burchell, was engaged in the Russian province of Esthonia collecting together a cargo of cattle for the English trade. He was in partnership with Mr. John Hönck and a Mr. Baker. The Estonian Agricultural Society had undertaken to supply Burchell with 800 oxen and 800 sheep. The Society collected 640 oxen at Revel, out of which 400 had to be chosen. 46 of these animals had travelled from St. Petersburg or its neighbourhood, in four horse waggons, but the remainder were Estonian oxen. The steamer 'Tonning' left London on the 9th or 10th of May, and arrived at Revel on the 16th or 17th. She left Revel with 331 oxen and 330 sheep selected by Mr. Burchell."

Professor Gamgee says—"I have taken considerable pains to investigate the documents relating to these transactions; and of the oxen chosen by Mr. Burchell, three were sold sick to a butcher named Siehbrett in Revel, one died, and a fifth was ill after the steamer had left Estonia.

"According to Burchell 13 of the 46 oxen from the interior of Russia were amongst those shipped for England. Mr. John Hönck says that all the cattle placed on board the 'Tonning' were Estonian. The St. Petersburg cattle were, however, mixed with the Estonian cattle at Revel; and although they might not be seriously ill, it is a well-known fact that Russian cattle infect others when they themselves are not suffering, or are very slightly attacked. The plague was in the vicinity of St. Petersburg at the end of 1864, and probably later.

"The oxen purchased by Mr. Burchell were to have been landed in London, but they were entered in the manifest for Lowestoft, 'so as to avoid the doctors.' I have seen a letter in which this sentence occurs. After all, the steamer made for Hull. The cattle were inspected at Hull; but it appears that, owing to the number being so very great, the inspection was not a very rigid one—600 animals having been inspected in three hours and a half by two inspectors.

"On the arrival of the cattle at Hull, Mr. Hönck 'put them in
the hands of a Mr. Coulson; who sold 106 of them to go to Derby or Leeds. A Mr. Hickman took 40 to sell at Manchester.

"The cargo arrived on the 29th of May, and the first 146 animals were disposed of on the 30th. The remaining 175 came to London, and they were sold on the Thursday following, after they had arrived in London on the Monday night." The cattle for London were placed in Mr. Hönck's lairs in York Road, adjoining the Cattle Market. They were then sold for slaughtering, with the exception of 20, which Mr. Baker sent on the following day to Gosport. The 155 animals were disposed of entirely to metropolitan butchers. The sheep were sold at Hull for killing purposes. The steamer 'Tonnings' was disinfected by the free use of chloride of lime, and after certain repairs were done to her engine, she started for Tonning. In a leading article in the Times, published on the 15th August, it is said that as far back as the 12th June animals affected with the steppe murrain were seen in the Metropolitan Market. As these were not the Russian cattle, they must have been animals which caught the disease in or near the market at the beginning of June. On the 19th of June, Mr. Carvell of Lambeth Walk purchased two cows, and one of these on the 24th showed signs of sickness."—(GAMGEE on the Cattle Plague.)

In the end of July the disease appeared in Aberdeenshire. It was brought there by four calves which were sent by train to Huntly from the south.

By the beginning of November the plague had been conveyed over the length and breadth of the land, embracing thirty counties in England, seventeen in Scotland, and one in Wales.

The following summary for the week ending December 30th will show how it had spread by the end of the year:—

Total number of farms, sheds, or other places in which the disease had appeared:—England, 7,443; Scotland, 2,065; Wales, 245. Total, 9,753.

Total number of cattle on farms, in sheds, or other places where the disease had been officially reported to exist:—England, 110,647; Scotland, 44,527; Wales, 4,536. Total, 159,710.

Number of animals slaughtered healthy:—England, 10,636; Scotland, 6,578; Wales, 152. Total, 17,366.
Total number of diseased animals reported since the commencement of the disease—

The disease continued to spread, and to commit great havoc, until an Order in Council was issued, making it compulsory to slaughter and bury all animals affected with the plague, as well as those which had been in contact with them.

The beneficial effects of this order were soon made apparent, the number of animals attacked gradually falling off until the disease was finally stamped out. It is true that every now and then outbreaks occurred at various places, without any trace of contagion or infection being discovered, leading people to think that the plague was a sporadic, non-contagious disease; and even to this day some believe that it was never imported here at all, and but for the most determined action of the Government, supported by the opinions of veterinary surgeons, all legislative restrictions upon the cattle traffic would have been removed.

Had the restrictions upon cattle traffic been removed, we should again have felt the effects of another visitation of the plague in 1872, for in July and August of that year the disease was brought to Deptford, Hull, and Leith, and but for the prompt action of the authorities, the affected animals would have conveyed the disease all over the country. As it was, the plague did appear at Patrington on the 10th, and at Yapham on the 19th of August. The origin of the outbreak was as follows:—

A vessel, the “Joseph Soames,” arrived in Hull on the 25th July, from Cronstadt, with fifty-eight oxen on board. Two, it is stated, had died on the voyage, and in consequence of information the cattle were examined by Professors Simonds and Brown, who found eighteen of them infected with the plague. On the
following day (the 27th) all the animals were slaughtered, and their carcases were placed on lighters and sunk. The hatches of these lighters were improperly fastened, and the carcases floated again, and were washed ashore on different parts of the coast. This washing ashore of the infected carcases caused much alarm, and it was feared the contagion would thus be conveyed. However, no evil results followed.

The origin of the disease at Patrington and Yapham is as follows:—"The ship with the diseased cattle on board was lying for two days in the Humber Dock, close to the 'Forin,' and not five hundred yards from the cattle market, and, in spite of all that could be done, there was an open communication between the vessel and the shore.

"For nearly a fortnight cattle affected with the plague had stood on the ship's—the 'Joseph Soames'—deck, and it is surely no exaggeration to say that the amount of contagium in the excretions which had accumulated was sufficient to infect every head of cattle in the kingdom.

"Is it necessary, then, to question the probability of some of the virus being carried into the Hull market only the day after the carcases of the Russian oxen were sent to sea? The precise manner of the conveyance of the poison has not been, and certainly will not be ascertained. No one, in short, saw one of the men who had been engaged about the diseased cattle rub his hand or coat against an animal in the market or on its way thereto. But when a centre of infection has been established, it is not usual to cavil much about the possible means of communication between that centre and a place a few hundred yards off.

"The next link in the chain of facts is the purchase of two animals, a heifer and a steer, at the auction sale in Hull market on July 29th, by a butcher at Patrington. These came from farms in the neighbourhood of Hull, where no disease had existed. They were taken by railway on the day of purchase to Patrington, and placed in a field adjoining one belonging to Mr. Sanderson, a miller, whose stock—two cows and two calves—were grazing in his meadow.

"Twelve days after reaching the field at Patrington, the heifer in the butcher's field was found to be ill, and was slaughtered on August 12th. A difficulty occurs here, which we hasten to
meet. Twelve days is a long time for the incubation of cattle plague; but we have to observe, for the information of our non-professional readers, that the date of the discovery of cattle plague is quite distinct from the real date of its outbreak in a herd."—(*Veterinarian*, October 1872.)

By the activity of the authorities the outbreak was confined to three infected districts, namely, Bridlington, Patrington, and Pocklington, to which places the disease was clearly traced by the writer of the article in the *Veterinarian*.

I think the origin of this outbreak is most clearly traced, and that the difficulty of the long incubative period (twelve days) is no difficulty at all, for in all probability the heifer had been more or less ailing for several days before the illness was discovered. I think it right to state that I have dwelt longer upon the history of this outbreak than perhaps was necessary, in consequence of Dr. Parkin in his work on Epidemiology having thrown discredit upon the source of origin, and stated most dogmatically that the disease was of spontaneous origin, and due to something to be mentioned in a book "to be shortly issued."

**TREATMENT OF THE CATTLE PLAGUE.**

The cattle plague may be classified as one of those diseases in which all methods of medical and hygienic treatment have hitherto proved unsuccessful; and, judging from the nature of the malady, always will prove unsuccessful.

The disease, when induced by inoculation, has proved of a less severe nature, and the per-centidge of recoveries has been greater in comparison than in that induced naturally. It has therefore been supposed that if inoculation were generally adopted (the disease never occurring a second time in the same animal), that the great mortality might be to some extent avoided. Professor Gamgee, however, concludes his exhaustive observations on this point as follows:

"*First.* Inoculation induces, as a rule, a mild form of disease amongst steppe cattle. In cattle of other breeds the loss has sometimes been slight, but is usually as severe as that arising from natural rinderpest.

"*Second.* The inoculated disease is communicable by re-inoculation and cohabitation. My experience would indicate
that the animals affected by simple cohabitation with inoculated cattle suffer more than those inoculated, and die in considerable numbers.

"Third. The results of inoculation are seriously aggravated by cold, wet, and exposure. The most successful cases have been those attended to indoors.

"Fourth. In my opinion inoculation never can be resorted to with success, even in Russia, as a means of exterminating rinderpest.

"Fifth. Means adopted for the cultivation or modification of the virus have proved unsatisfactory, and cannot be relied on.

"Sixth. Any liquid from the body of a sick animal serves to communicate the disease by inoculation.

"Seventh. The period of incubation is usually from four to five days after inoculation, and the invasion of the disease is indicated, first, by elevation of temperature, and secondly, by distinct white epithelial eruptions on the inner side of the lower lip, below the corner incisor, and on the inside of the nose.

"Eighth. The cutaneous eruption not constant in natural rinderpest is usually seen in inoculated animals.

"Ninth. Sheep can be inoculated from cattle, and then again cattle from sheep, without modifying the virulence of the virus.

"Tenth. I have not witnessed any modification in the inoculation with different secretions. I have tried blood, milk, abdominal fluid, contents of the intestines, frothy mucus from the windpipe, saliva, and tears.

"Eleventh. I have reason to believe that glycerine modifies and then destroys the virus, as in the case of pleuro-pneumonia. On this point further experiments are required, but I feel tolerably certain that mixing glycerine with the virus of rinderpest cannot be relied upon to obtain a mild form of the disease.

"Twelfth. All animals that escape after inoculation without indicating symptoms, such as elevation of animal heat and eruption in the mouth, are not protected from further attacks.

"Thirteenth. The produce of animals which have had rinderpest is as susceptible to attacks as any other.

"Fourteenth. Age does not materially affect the results of inoculation."—(Gamgee on the Cattle Plague.)

Seeing then that the cattle plague is beyond the power of all medical and hygienic remedies, and that the inoculated disease
commits fearful havoc amongst stock, we can only trust that the Government of this country will ever remain uninfluenced by those who would wish that cattle were admitted from all parts of the world without any restrictions whatever, and carefully guard our coast from another visitation of this dreadful malady; but should it again have access to our shores, there is only one method of dealing with it, and that is to stamp it out, by destroying all affected with it, as well as those which have been in contact with them.

In conclusion, I feel in duty bound to pay my tribute of respect to Professor John Gamgee for the earnest endeavours he made, as far back as 1857, to rouse up the Government to the fact that this country would be visited by the cattle plague if measures were not taken to prevent its entrance. I am aware that Professor Gamgee received much abuse, but he was a true prophet, and if he has received no other reward, has the satisfaction of knowing that he has performed an important public service.

BINDERFEST IN SHEEP.

It was at one time affirmed that cattle only were subject to the plague, "the cattle tribe being alone its victims."—(Simonds' Report to Agricultural Society, 1857.) Experience has, however, proved that sheep, though less susceptible, are still capable of being affected with the plague.

The symptoms are the same as in the ox, and any one familiar with the disease in the latter animal will at once be able to recognize it in the sheep. The incubative stage is more variable than in cattle; the disease induced by inoculation appears in from five to eight days; naturally caused by cohabitation or contact, in from five to twenty days. Sheep kept in fields with cattle suffering from the plague remain a long time unaffected with the disease, many escaping it altogether; but if kept in closed sheds they are almost certain to become affected in a very short time.—(Professors Vrakel and Pritchard, Report to Commissioners, 1866.)
CHAPTER XVII.
CONTAGIOUS DISEASES—continued.
PLEURO-PNEUMONIA CONTAGIOSA.

Definition.—A contagious febrile disease, peculiar to horned cattle, supposed to have originated in Central, and has been conveyed to all parts of Continental Europe, to Britain, Africa, America, Australia, India, and New Zealand. It is due to a contagium, which gains access to the system by the lungs, and which after an incubative period of from two to three weeks to as many months, induces complications in the form of extensive exudations within the substance of the lungs, and upon the surfaces of the pleura, finally resulting in consolidation of some portions of the lungs, occlusion of the tubes, embolism of the vessels, and generally adhesion of the pleural surfaces. In some cases there is extensive and rapid destruction of lung tissue, with death from suffocation; but most commonly the disease is of a lingering character, symptoms of great prostration manifesting themselves, with blood poisoning from absorption of the degraded pulmonary exudates, and death from marasmus and aspasia.

Synonyms.—Lung disease, pleura, new disease, new delight (Yorkshire), pulmonary murrain, epizootic pleuro-pneumonia, &c.; called by the Germans lungen seuche and peri-pneumonia exudativa contagiosa; by the French maladie de poitrine du gros bétail and pérîpneumonie contagieuse.

PATHOLOGY AND SYMPTOMS.
There is much variety in the manifestations of the disease. In some instances, more especially during its first outbreak in a
district, it runs a rapid course, destroying life in the course of a few days, the lungs after death presenting the appearance of a congestive inflammatory change, with embolism and haemorrhagic infarction. In other cases—and these are the most numerous—the onset, course, and termination of the disease occupy a period of from two to eight weeks, or even longer, the animal becoming much emaciated, and finally succumbing to an exhausting diarrhoea; imperfect aeration of its blood; hydrothorax; the depressing influence of degenerated animal matters absorbed into the blood, and anemia.

Premonitory symptoms of the disease.—Similar to the cattle plague, the commencement of the disease is often not observable. Thus attention is only called in many instances to an animal for the first time appearing unwell, but in which an examination brings to light the fact that changes of structure have taken place, to such an extent as to convince the observer that disease has been gradually increasing for a lengthened period. The thermometer is not even a true guide by which we are able to discover the end of the incubative and the beginning of the active stage, as later investigations have proved that extensive pulmonary changes may exist without elevation of temperature, and that the fever is probably concomitant with the invasion of the pleural surfaces. For example, the introduction of the disease into Australia from this country proves that the first manifestation of illness is not at all to be depended upon as a guide to its true commencement; for the carriers of the contagion—bulls for breeding purposes—were three months on the voyage, the disease only breaking out after they were landed; but it is of great importance that thermometric observations should be made during the prevalence of pleur- pneumonia, in order that owners of stock might be warned in time, and that measures be taken to isolate or otherwise dispose of all animals in which the temperature is found to be rising. In a suspected herd, all animals showing a temperature above 102° should be carefully watched. If the heat rises above this, there can be little doubt that disease is at work. When the disease is established the temperature may rise to 105°, 106°, and rarely to 107° F. In 154 cases, 61 of which were recorded by Mr. Elphick, V.S., Newcastle, and the remainder by myself, only in 8 did the temperature reach 107°.

</table>

The palpable or obvious symptoms are slight rigors or shiverings, the hair merely standing the wrong way, loss of appetite to some extent, secretion of milk diminished; in some cases the animal "knuckles over" at one hind fetlock, usually the right one; an occasional cough is heard, which is dry and hard in character, not the painful cough of pleurisy, as one would suppose, nor the moist hoarse cough of inflammation of the bronchial mucous membrane; rumination becomes irregular, and although there is some loss of appetite, the animal seems fuller than its fellows, which are healthy and eating vigorously. The bowels are rather constipated, and the urine is scanty and high coloured.

The pulse of cattle, as I have already stated, is not, more
especially with regard to its number, a good guide to the practitioner in this or any other disease; however, as it advances, the pulse becomes accelerated and of a feeble character—sometimes a large soft pulse, sometimes a small wiry one. These insidious symptoms may continue for several days, the most careful examination of the chest denoting nothing unusual except a tenderness upon pressure applied to the intercostal spaces of one or both sides, and pressure upon the back causing the animal to wince and perhaps give a slight groan. Some cases in an infected herd will at this stage begin to give obvious signs of recovery, and in a few days seem well again, the morbid material having evidently been expelled from the body without causing any extensive pulmonary change. In all cases, however, some amount of irritation and alteration of the lung tissue has been induced, as a cough remains for some time longer. These cases, however, are a source of great mischief, as they become the media through which the virus continues to be conveyed to the cattle with which they are herded, for a considerable period after their apparent recovery. Should recovery not take place, the signs of general disturbance gradually, sometimes rapidly, increase; the cough becomes more persistent, the mucous membranes, except that of the nose, are generally pale, the respiratory movements increased in frequency, more abdominal and shallow; when the animal stands, the elbows are turned out, the nose extended, back arched, and the hind limbs drawn under the body and knuckling over at the fetlocks; when recumbent, the animal throws the weight of its body upon the sternum, and, owing to the anatomical conformation of this bone and its articulation with the true ribs, the chest is thus expanded.

The breathing becomes painful, and is often accompanied by a moan or grunt, emitted during each expiration, and the nostrils are dilated; but even these signs are not constant, many animals with extensively consolidated lungs being but slightly distressed in the breathing when left quiet; but accelerated respirations are easily induced by percussion applied to the sides, or by compelling the animal to move. A discharge sometimes issues from the eyes and nose, which is at first colourless, but often becomes purulent and yellowish, but is seldom profuse. The extremities, as well as the horns and ears, vary much in temperature. Sometimes all are cold; often, however, one ear and
one horn may be cold whilst the others are hot, and so on with the extremities. The surface of the body becomes harsh and dry, the skin appearing tightly bound to the subcutaneous structures, and there is rapid loss of flesh. Constipation of the bowels continues in many instances for a long period; in others it is succeeded at an early stage by a diarrhoea, which, if not too persistent, seems to have a salutary effect; but if it assume the colliquative character, the animal dies in from two to three weeks from the first visible manifestation of the symptoms.

The physical signs upon percussion are tenderness and some amount of dulness, the dulness increasing in proportion to the exudation and consolidation. If at the outset of the disease it can be determined that both lungs are inflamed, the prognosis in all cases is unfavourable; but if, on the contrary, it can be demonstrated that but one lung is affected (the right lung, according to my experience, being more prone to suffer, but showing a greater tendency to recovery), there are some hopes that the case may recover, for very frequently the morbid action is confined to the side primarily attacked.

Auscultation will detect friction and other sounds, which indicate that the disease is not confined to the pleural surfaces; thus we have crepitations, both large and small, indicative of inflammation of the lung connective tissue, with ronchus and sibilus, denoting bronchial disease. It is seldom, indeed, but that some sound or other is detectable in all parts, except the lower portions, of the chest; the consolidation of the lung, extensive though it may be, being insufficient to mask or hide the abnormal sounds emitted by the lung tissue, pleura, or bronchial tubes.

When the disease is confined to one lung, the respiratory murmur in the healthy lung is louder than natural, owing to its having to admit more air than when both are in a state of health. This must not be confounded with a diseased condition; and in order not to make a mistake, percussion must be applied,—the healthy side will be resonant, the diseased one dull. I have seen some cases where the diseased and consolidated lung has enlarged to such an extent as to push the ribs immediately covering it outwards to some extent, the animal appearing rounder and larger on that side in consequence; and some of these cases have afterwards thriven and become fit for the butcher.

Now and then it is found that some portion of the lung
CONTAGIOUS DISEASES,

becomes gangrenous, and is coughed up; these cases are, however, very rare. When gangrene occurs, the discharge from the nose is sanious and fetid, and a fetid diarrhoea soon carries off the suffering beast. Abscesses in the lungs are an occasional consequence. An animal apparently recovers from the disease; but after a time begins to lose flesh, and sinks from exhaustion, the post mortem revealing caseous tumours or a large abscess or abscesses in the lungs. Another termination is the formation of groups of tumours upon the pleural surfaces, more especially that portion of them covering the anterior aspect of the diaphragm, upon the pericardium, and the peritoneum. These tumours are known amongst butchers and others as "grapes," and are supposed to be due to the tubercular diathesis. There is no doubt that sometimes these deposits are essentially scrofulous, and are caused by that condition of the body independently of pleuro-pneumonia; in other cases it is to my mind beyond a question that they are secondary growths, resulting from the absorption of the altered or degenerated exudates of pleuro-pneumonia. They will be referred to hereafter. In some instances of very extensive consolidation, the sounds detectable by auscultation and those emitted by percussion are very trivial. In such it is found that the alteration of structures is most extensive in the central portion of the lungs. One symptom is very diagnostic of this condition—namely, much coughing when the animal attempts to swallow: this is caused by the exudate pressing upon the oesophagus within the chest, and retarding the action of deglutition. When the exudate presses upon the large blood-vessels, there may be turgescence of the jugulars and the venous pulse.

POST MORTEM APPEARANCES.

On opening the chest of an animal which has been slaughtered early in the disease, the visible changes are dulness of the affected pleural surfaces; the substance of the lungs, particularly of the large lobes, is red congested, and more or less consolidated; the redness and congestion being often in patches, each patch being generally surrounded by whitish bands of thickened interlobular tissue, giving them a marbled appearance. In other instances the redness is diffused over a more or less extensive surface, and is due to staining of the interlobular bands by extravasated blood, one or several affected lobules forming one patch, whilst the lung
tissue for some distance may be more or less healthy, until another
patch of more or less consolidated tissue is arrived at. The groups
of consolidated lobules vary much in colour, some showing the
deep redness of recent inflammation, whilst others present signs
that the exudation is not only consolidated, but is undergoing a
gradual metamorphosis—softening—by which it is changed into
a whitish turbid fluid, which flows from the cut surfaces, and is to
some extent capable of being absorbed. We have thus the red and
the grey hepatization, the red denoting the early, the grey the
more advanced stages of the inflammation; but the true grey
hepatization is seldom or never seen now-a-days, as cattle are
slaughtered before the exudate has undergone this change.

In some animals from an affected herd it has been noticed
that the first change is a dilatation of the blood-vessels, and the
lung assumes a scarlet colour. There is no exudation into the
interlobular connective tissue, but the lung is increased in
weight, and sinks further in water than healthy lung.

In pleuro-pneumonia of the horse, which has continued for
some length of time, a marbled appearance is frequently noticed,
but not to such an extent as in the ox.

The true grey hepatization seems to indicate a drying up of
the inflammatory produce, and a formation of a large amount of
new connective tissue in the lung, and the disappearance of
the alveolar spaces; but the apparent grey or marbling hepa-
tization seen in the early stages is due to a distended state of
the interlobular lymph vessels surrounding the infarction in
the lobule.

The peculiarities in the character of the inflammation of
pleuro-pneumonia are its tendency to invade small groups of
lobules, more especially those composing the large lobes, or
even a single lobule, and to spread not only by diffusion, but
also by the invasion of non-contiguous lobules. In this respect
it simulates to some extent the pulmonary inflammation in-
duced by the glanders poison, and is characteristic of a local
change depending upon a cause existent in the blood; and
we may conclude that the true nature of the inflammation
differs from that of an ordinary one; that it is secondary to a
general infected condition; that the exudates do not tend to
become highly organised, but rarely to become gangrenous, and
generally to change to cicatricial tissue, or degrade into lower
forms of matter—i.e., caseous or calcareous—and to remain latent
in the part for an indefinite period; and that it may commence
primarily in the parenchyma of the lungs, and that finally the tubular portion and vessels of the lungs become obliterated, not only by the pressure of exudates external to them, but by histological elements and clots within them. In consequence of these changes, the diseased lung becomes very heavy, sometimes attaining the weight of twenty, thirty, or even fifty pounds, sinks in water, is resisting, solid, non-crepitant, and on section presents the marbled appearance already mentioned.

In those rapid cases of death which occur after the first introduction of the disease into a locality, the changes in the lung tissue are those of an acute character: there is great redness or blackness of the parenchyma—haemorrhagic infarction—which is at same time loaded with much serosity, and is very friable, soft, and easily broken by the finger; but in the examples which most frequently fall under the pathologist's notice the cadaveric lesions are—1st. Extensive deposits of yellowish, friable layers of false membrane upon the surface of the pleura and upon the pericardium. These false membranes exist upon one or both sides, as the case may be. Portions of the lungs are found adherent to the sides and to the diaphragm, but in many cases the bands of lymph are of a friable nature, the adhesions very imperfect, and the opposing surfaces easily separated, while there is generally much fluid in the cavity of the thorax, in which flakes of fibrin are seen floating. The effused fluid is of a yellowish colour, contains much albumen, and if exposed to the atmosphere, will often coagulate into a gelatinous clot. There is much variety in the quantity of the fluid. In some cases the pleural cavity and pericardium will contain several gallons, whilst in others the quantity may only measure a few ounces.

The pulmonary pleura, in addition to the bands of lymph, which form the adhesions already alluded to, is invested by a firm layer of lymph, which may be stripped off, leaving the lung rough, mottled, and having papilla-like eminences upon its surface. These bands of lymph, as well as the flakes found floating in the serum, are composed of fibrin. When examined microscopically, cellular elements, partaking of the nature of pus cells and white blood globules, are seen imbedded in the fibrin, which is sometimes granular, but often filamentous. The turbidity of the serum is caused by these globules and some amount of fatty matter.
PLEURO-PNEUMONIA.

The tissue connecting the pleura to the thoracic walls is but slightly involved, and when removed after slaughter, the underlying structures seem healthy, but a careful examination of the part will show the ribs to be bare, stripped of their pleural covering, and to have an unnaturally clean whitish appearance, and the flesh, in advanced cases, unhealthy, moist, or even dropscical. The pericardium is also covered with flakes of lymph, and the areolar tissue connecting the cardiac fat is greatly thickened by exudative materials.

It has been considered that the primary seat of the disease is situated in the pleura; that the inflammation is of a rapidly spreading character, causing the formation of what have been termed by Rokitansky "the croupy exudates," both upon the surface of the serous membrane and in the substance of the lungs. As a rule the inflammation in pleuro-pneumonia contagiosa is more pronounced in the parenchyma than upon the pleural surface; but this is liable to exceptions, for in some cases the pleural disease is more marked than the parenchymatous. Some writers think that the disease may begin in the bronchi and air cells, and that the irritation extends from the tubes and cells into the parenchyma and pleura. Their conclusions are based upon the fact that inflammatory new formations are generally found, in the advanced stages of the disease, in the air vesicles, blood-vessels, and bronchi, as well as in the other portions of the inflamed part.

The most recent observations on the pathological anatomy of pleuro-pneumonia are those of Professor Yeo, London, who has furnished an elaborate report, published in the Veterinary Journal and other periodicals.

Dr. Yeo divides the lesions as follows:—"Morbid processes occur in the pleura, in the lung parenchyma, and in the bronchial tubes and blood-vessels;" and concludes his observations as follows:—

"To recapitulate, then, the various items in the pathological sequence may be thus enumerated:—

"1. Irritation of the mucous membrane of the smaller bronchi, probably by some infective material (specific virus?).

"2. Chronic ulcerative bronchitis, localised to a few minute bronchi.

"3. Occlusion of the affected air-tubes."
"4. This produces such changes in the air-cells belonging to the affected tubes that the lobular parenchyma becomes solid.

"5. As the bronchial disease progresses, the walls of the air-tubes become thickened and infiltrated with the products of chronic inflammation.

"6. The peribronchial lymphatics are implicated by the extension of the infective process from the bronchus, and are soon filled with dense exudation.

"7. The block in the lymphatics of the broncho-vascular system impedes the flow of lymph from the corresponding territory.

"8. The tributary lymph-channels are thus mechanically engorged, and at the same time they are irritated by infective materials.

"9. The inflammation of all the coats of the air-tube gradually spreads towards the root of the lung.

"Thus we have a deep-seated cone of typical consolidation, traversed by numerous wide whitish lines, corresponding to the swollen interlobular connective tissue (marbling). In fact, the essential features of the disease are all established.

"The morbid process seldom stops here, however. It spreads in two ways.

"First, by the broncho-vascular lymph-passage:—

"1. The irritating and infective materials find their way along the lymphatics towards the root of the lung, following the normal course of the lymph stream.

"2. The wall of the bronchus becomes affected after a time by the irritative matter in its surrounding lymphatics.

"3. The lymphatics of tributary bronchial tubes met with as the disease thus advances are choked, and the drainage of their territory impeded.

"4. The interlobular lymph spaces of the newly affected territory soon become filled with exudation. Thus the clear kind of consolidation is produced.

"Secondly, by the pleura:—

"1. The pleura becomes affected over the focus of consolidation by means of the subjacent lymphatics.

"2. The pleurisy soon extends far beyond this limited region, or the serous membrane becomes generally inflamed.

"3. From the inflamed pleura infective materials reach the lymphatics beneath it, and also those lying between the neighbouring superficial lobules.
"4. Extending along the interlobular lymphatics, the irritation and exudation may pass towards the deeper parts, so that an immense tract of lung is converted into a semi-translucent mass with swollen interlobular spaces.

"The consolidation formed in any of these ways may become intense induration, if the animal lives long enough.

"With regard to the origin of the disease of the vessel-wall we must also start from the peribronchial disease.

"1. The lymphatics of the bronchus readily allow the morbid products to pass to those immediately around the vessels.

"2. The wall of the vessel becomes greatly thickened by chronic inflammatory products.

"3. The inner coat—which resists the disease for some time—ultimately becomes diseased in small patches.

"4. The blood coagulates over the diseased inner coat, and may occlude a small branch at its origin, or even the entire vessel.

"5. Particles of the clot may break off, and, passing into the minute arteries, form their embolic plugs.

"6. Thus numerous arteries of varying size may be stopped up.

"7. The most varied forms of hæmorrhagic infarction are thus produced.

"8. The infarction may become gangrenous, cheesy, or may dry up into a crumbling mass.

"9. A capsule may form around the most diseased part, and shut it off from the rest of the lung.

"If asked to give a pathological definition of pleuro-pneumonia, I should say that it was—A chronic, specific, local disease, starting in the bronchi, and insidiously implicating the parenchyma of the lung by occlusion of the bronchi and inflammation extending along the lymphatics: the other organs and the blood possess a singular immunity from the specific contamination. It is not accompanied by constitutional symptoms, and only gives obscure physical signs. At any time during the progress of the disease its existence may be manifested clinically, by the occurrence of complications—acute pleurisy or hæmorrhagic infarction with pleural inflammation—which excite high fever, with various functional derangements."

A reference to the observations of Dr. Yeo, excellent as they are in many particulars, will show that they are open to grave objections.
In the first place, he concludes that the disease originates in
the bronchial tubes, and that the surrounding tissue is in a
state of chronic inflammation for a lengthened period before any
symptoms are manifested. He says—"I am convinced that the
lung disease usually exists for months without being suspected,
and invariably the beast is first thought to be sick only when
the affection has spread to the pleura, and caused intense
inflammation of that membrane with its accompanying well-
marked symptoms."

These very confident conclusions of Dr. Yeo, if allowed to go
unchallenged, are calculated to lead to much misapprehension,
and even to actions at law. They prove to me that he has had
but little or no opportunity of studying the disease in the living
animal, and that he bases his conclusions upon what he has
observed in the laboratory.

Now, if pleuro-pneumonia were a species of bronchitis, or, as
he puts it, if the virus acted primarily on the bronchial mucous
membrane, one would naturally conclude that the bronchi
would in the earliest stages show evidence of disease; but such
is not the case, and only occasionally do we meet with con-
gestive patches along their course in those parts of the lungs
already involved in the disease. As the disease advances,
however, the bronchi, as shown by Dr. Yeo in the woodcut,

† The cut was kindly sent me by Mr. Fleming.
become occluded, their walls invaded by the inflammation, and they, as well as the alveoli and air cells, are filled with a solid exudate, differing, however, from that of bronchitis, where the occluding material is composed of more or less fluid catarrhal products; but this occlusion, however, is a secondary process, the tubes in the non-consolidated portion of the lung—although the earlier phases of the inflammation might be established in its parenchyma—rarely showing any evidence of disease. In some instances, rarely met with since early slaughter has been made compulsory, the bronchial tubes of a non-invaded lung territory are found occluded, and the lung tissue surrounding them collapsed by the gravitation or entrance into them of the degraded, softened products of the pneumonia, which, having escaped from the seat of formation, have been forced by the inspiratory act into the healthy tubes. Here we certainly find the bronchi filled with diseased products, and the pleural surface presenting little or no signs of disease; but an examination of the pneumonic products will at once prove that they consist of degraded, softened, inflammatory exudates, and that the parenchymatous disease is antecedent to the occlusion of the bronchi. In the second place, Dr. Yeo concludes that, in the common run of cases where pleurisy is associated with extensive disease of the lung, the latter gives the impression that it is of much older standing than the pleural affection. He says, "The pleurisy is commonly acute; while in the lung we usually have evidence of such chronic change as would require a very long time for their development."

If Dr. Yeo had had clinical experience amongst cattle he would have seen that these conclusions are quite opposed to facts. Many instances have occurred in my experience where animals, apparently healthy, which had been slaughtered in consequence of having been in contact with others affected with pleuro-, have presented, post mortem, round patches of consolidation in one or more parts of their lungs, always associated with pleural exudation, and sometimes even adhesion of the opposing pleural surfaces; indeed, in some instances the most pronounced evidences of the presence of the disease have been patches of pleural exudation with but little or no corresponding invasion of the lung parenchyma.
Then, as to the chronicity of pleuro-pneumonia, the statements of Dr. Yeo are against all clinical facts, and consequently must not go unchallenged. A reference to the accompanying woodcut, and a short history of the case from which it was obtained, will illustrate this point. The large dark patches

**Fig. 5.—** (a) Pleural surface presenting a smooth opaque appearance. (b) Subpleural exudation. (c) Red consolidation. (d) Thickened interlobular tissue. (e, f) Hemorrhagic spots, due to extravasation into alveoli.

**Fig. 6.—** (a, c) Exudation in air vesicles, composed of a fibrinous network, with leucocytes lying in it. (b, d) The same caseating. (e) Air vesicle filled with leucocytes only. (450 diam.)

In the centre is seen a blood-vessel filled with a fibrinous plug, and around effusion of leucocytes in the substance of the wall of air vesicle.
reveal the condition of black consolidation, and the smaller ones the commencement of that process, which is evidently that of haemorrhage into the alveoli; the dark patches are surrounded by oedema of the tissue contiguous to the points of extreme congestion; the interlobular connective tissue is much thickened, and if carefully cut, a quantity of straw-coloured lymph, only found in recently invaded lung territory, flows from the cut surface. This may be collected and used for inoculation purposes. The pleural surface is much thickened, the exudate being both within and upon the serous membrane. Microscopically examined, as shown in fig. 6, the diseased products have every appearance of being of recent origin, the secondary or degenerative changes (b, b), which occur very early in pleuro where the blood supply is cut off by plugging of the blood-vessels, having only commenced. The history of the animal from which the specimen was obtained was clearly traced. It had been brought from a healthy herd six weeks prior to slaughter, throve and milked well up to two days prior to slaughter, when it presented slight signs of illness, became rapidly worse, and when examined clear evidence was obtained that both lungs were gravely invaded. I may state that, along with four others, all of which succumbed, the animal had been brought into a byre where the disease had previously prevailed, but which had been declared free under the Act of 1868. Taking into consideration the clinical fact, which has forced itself upon me upon many occasions, that it generally takes from a month to six weeks (see pp. 184-5) for the disease to develop in a healthy animal introduced into an infected byre, and the condition of the diseased products in the above case, one cannot help concluding that pleuro-pneumonia is often a very acute disease, and that it may rapidly involve large tracts of lung tissue.

In other instances, however, the invasion is confined to small areas; the disease may then assume a mild type, and the animal recover; or a chronic character, from which it eventually succumbs, not so much from destruction of lung structure, but from a mal-condition of the whole system, arising from absorption of the degraded products of the inflammation.

The cause of pleuro-pneumonia, in this country at least, is
undoubtedly contagion and infection, and these only. My experience of the disease enables me to state that no mis- management with regard to feeding, housing, or the general treatment of stock, will induce an outbreak of pleuro-pneumonia contagiosa.

I do not say, with some writers, that it nowhere originates spontaneously; but I do say that it never originates spontaneously in this country.

That pleuro-pneumonia is both contagious and infectious has been proved by direct experiments performed in France, reported by Professor Bouley.

"The first series of experiments was conducted at Pomerage, in the well-known and vast domain of Rambouillet. The whole is enclosed by walls, surrounded by woods, and perfectly isolated. A stable was separated into two distinct compartments. In the first, designated A, with a south-west exposure, was a single door, leading out on a sufficiently wide plot of ground, bounded by water, where the cattle could be taken to drink. Every precaution was taken to prevent the cattle in A from coming within reach of those in the second stable B. The latter was situated to the left of A, and completely separated by a solid wall.

"Pleuro-pneumonia had never existed in the commune of Rambouillet.

"Messrs. Renault, Delafond, and Jouet chose the cattle, and subjected them to a close examination. The herd consisted of three bulls and seventeen cows. These animals were distinguished by names and numbers, and distributed in the two stables in relation to age, breed, and sex, so as to secure an equable distribution. Three sick cows were sent to Rambouillet on the 14th of November 1851—one from the Département du Nord, the second from Mont Souris, and the third from Vaugirard. Three more sick cows were sent on the 2d of December 1851.

"Of these six sick animals, three died and three recovered. One lived three days in stable A, a second five days and a night in the same, and the third, in stable B, survived ten days and two nights.

"Of the three sick cows that recovered, one, admitted into stable A on the 10th of November, presented symptoms of the
malady up to the 20th of November, viz., for thirty-four days. The second entered stable B on the 2d of December, and was sick for nineteen days. The third, also admitted into the same stable, continued ill for twenty-eight days.

"Stable A.—On the 21st of November 1851, viz., only six days after the introduction into this stable of two sick cows, a peculiar cough was shown by two cows ('La Noire,' No. 16, and 'Norma,' No. 2). Their lungs appeared sound, and they continued to eat and ruminate. The same symptom manifested itself successively as follows:—

"First. On 'Coquette' (No. 3), on the 22d of November.
"Second. On 'Rosine' (No. 9), on the 23d of November.
"Third. On 'Berthe' (No. 8), on the 25th of November.
"Fourth. On 'Babet' (No. 7), on the 3d of December.
"Fifth. On 'Clara' (No. 1), on the 5th of December.
"Sixth. On 'Olga' (No. 6), on the 7th of December.
"Seventh. On 'Marton' (No. 5), on the 10th of December.

Thus, twenty-four days after the admission of two sick cows, and eight days after the introduction of a third sick animal, out of ten healthy animals, nine presented the abnormal indication of a peculiar cough. Only one cow ('La Caille,' No. 11), continued in perfect health. After the first sign of sickness, the characteristic symptoms of pleuro-pneumonia appeared in six cows in the following order:—

"First. 'Olga' (No. 6), thirty-one days after first contact.
"Second. 'La Noire' (No. 16), thirty-two days after first contact.
"Third. 'Clara' (No. 1), thirty-five days after first contact.
"Fourth. 'Rosine' (No. 9), thirty-five days after first contact.
"Fifth. 'Norma' (No. 2), thirty-seven days after first contact.

Of these six animals only one died, viz., 'Olga' (No. 6), and her carcass was removed to Alfort on the 6th of January, and there dissected by the members of the commission. Of the five other cows in the stable, the reporters say that symptoms of variable intensity and duration appeared. Certain lesions were, however, recognised some time after by dissection.

"Of the three animals ('Berthe,' No. 8, 'Babet,' No. 7, and 'Marton,' No. 5), which began to cough the first day after contact with the sick cows, the only symptom which lasted, and is said to have continued for several months, was the cough.
"Stable B.—On the 25th November 1851, viz., nine days after the introduction in stable B of the two sick cows (Nos. 23 and 24), the healthy cows began to cough in the following order:—

"First. 'Suzon' (No. 13), on the 26th of November.
"Second. 'La Garde' (No. 20), on the 23rd of December.
"Third. 'Marton' (No. 5), on the 3rd of December.
"Fourth. 'Kettley' (No. 17), on the 7th of December.
"Fifth. 'Leduc' (No. 18), on the 10th of December.
"Sixth. 'Nebula' (No. 4), on the 18th of December.
"Seventh. 'Homard' (No. 14), on the 28th of December.

"So that, thirty-two days after the introduction of sick cows in stable B, out of ten healthy animals, seven presented the peculiar cough before mentioned.

"Three animals ('Junon,' No. 19, 'Bringé,' No. 10, and 'Biche,' No. 12) continued in perfect health.

"Well-marked symptoms of pleuro-pneumonia presented themselves on four cows in the following order:—

"First. 'La Garde' (No. 20), sixteen days after first contact.
"Second. 'Leduc' (No. 18), thirty days after first contact.
"Third. 'Marton' (No. 5), thirty-five days after first contact.
"Fourth. 'Homard' (No. 14), forty days after first contact.

"Two of these animals died after nine days' illness. The other two were quite convalescent in twenty-eight and thirty-five days respectively. The three other animals continued to cough for some months without manifesting more serious symptoms.

"The conclusions drawn by the French Commissioners from the foregoing experiments were as follows:—

"The epizootic pleuro-pneumonia of cattle is susceptible of transmission from sick to healthy animals by cohabitation.

"Twenty per cent. of the animals manifest a resistance to the contagion.

"Eighty per cent. manifest various effects of the contagious influence.

"Fifty per cent. are seized with decided symptoms of pleuro-pneumonia, and of these fifteen per cent. succumb, and thirty-five per cent. recover.

"Immediate contact is not necessary for the transmission of
the disease, and the first affected were among the furthest removed from the sick."

The proofs of the contagiousness might be multiplied ad infinitum. The above enumerated experiments, directed as they were to the purpose, are, in addition to what is of every-day occurrence, to my mind quite sufficient.

TREATMENT OF PLEURO-PNEUMONIA.

It may be broadly stated that the course and progress of this malady are but seldom benefited by the administration of drugs, or the application of external irritants. Many of the so-called cases of pleuro-pneumonia, which are said to be cured by active interference, are, generally speaking, cases of indigestion. Much good may be done, and many animals are tided over the critical stage of the malady, by the enlightened and rational supervision of a veterinary surgeon; but it is worse than useless for any one to endeavour to cut short the duration of the disease. If during the early stages there be much fever, the severity of the febrile symptoms may be subdued by repeated ten-drop doses of Fleming's tincture of aconite freely diluted. If there be constipation of the bowels, it ought to be removed by gentle oleaginous purgatives; at all times tympanitis of the stomachs must be relieved by the administration of the carbonate of ammonia, or even by puncturing the rumen. Indigestion must be prevented, and this is best done by the withdrawal of all food whilst rumination is suspended. I have known cases do well, and never have tympanitis, where solid food of every kind has been withheld for periods varying from twelve to twenty days; the patient receiving nothing during the greater part of the time but a plentiful supply of cold water, and cold linseed tea or cold gruel, when these would be voluntarily taken. If the animal would not drink the gruel or linseed tea, or whenever it seemed not to relish them, a return was made to the cold water. After the patient had commenced to "chew the cud," solid food was given very sparingly for some time. Slight diarrhoea occurring early in the disease may be looked upon as a salutary effect, and is not to be interfered with; but when caused by drastic cathartics, the forcible horning of gruel, or other improper treatment, it generally does much harm by causing early debility,
and must be gradually checked by chalk, opium, or the more powerful astringents, catechu, tannic acid, &c. When convalescence has commenced, strength may be increased by small doses of sulphate of iron given mixed with the food, which must be good and easy of digestion. Good hay or grass, or linseed cake, are the best; roots, such as turnips, being apt to cause some gastric or intestinal irritation. In cases characterised by much debility, strength may be rapidly restored by the daily allowance of a dozen eggs, given either mixed with the food or beaten up with milk; generally the animals will drink the milk voluntarily, and become very fond of it.

An extensive experience has convinced me that where both lungs are affected the disease terminates fatally; that many animals recover where one lung only is diseased; and that the various methods of treatment which have been recommended and tried have never done any good, never increased the number of recoveries, but have often done much harm.

At one time I thought I had made a happy discovery, and that carbolic acid given internally was going to do wonders, some cases having been apparently much benefited by it. Further experience, however, proved that, like other remedies, it was no panacea. I have tried the neutral salt, the tonic, the astringent and mineral acid treatments, and can safely state that they—as well as bleeding, blistering, setoning, &c.—are, on the whole, useless. There are occasions where neutral salts, tonics, or astringents are calculated to modify some symptom of the disease, or to remove the cause of some aggravation, and thus tend to ameliorate the suffering of the animal; but nothing can be said to exert a really curative effect on pleuro-pneumonia.

**PREVENTION OF PLEURO-PNEUMONIA.**

When the disease breaks out in a herd, the affected animals are to be isolated, or, if “in condition,” slaughtered for beef, experience having proved that such beef is good and wholesome if the animal is killed early in the disease. If the animal be out of condition, slaughter and burial are the safest, and, in the end, the most economical; indeed, it may be distinctly laid down that the slaughter of the whole herd for human food is the cheapest in the end, the hides, hoofs, &c., being care-
fully kept from coming in contact with any healthy cattle. Some recommend the destruction of hides, hoofs, &c. I think this a wasteful destruction of property, and fail to see how the disease can be propagated by them; unless, indeed, they are actually brought into contact with healthy cattle—not a very likely occurrence.

Disinfection.—All sheds, cow-houses, or other premises which have contained cattle affected by the lung disease should be thoroughly cleansed and disinfected. The best and cheapest way of doing this is—1st. To burn sulphur in the buildings; 2d. To whitewash the walls, stalls, roofs, and every nook and crevice within the building with lime-wash containing carbolic acid (crude), in the proportion of one pint to each bucketful of whitewash.

Inoculation of Pleuro-Pneumonia.—If the present legislative enactments fail to prevent the spread of the malady, it will be time for compulsory measures to be instituted to test the value of inoculation. It is strongly recommended by some Continental writers and by some English veterinarians of skill and experience. My friend Mr. W. Lewis, V.S., Crewe, is a strong advocate for it, and no one is calculated to speak with greater authority, as he has been in extensive practice in one of the greatest cattle counties (Cheshire) for many years, as well as being the consulting veterinary inspector for the county. I understand it has been practised for many years in some of the London dairies, and has latterly been in vogue in Edinburgh and neighbourhood, and the results have so far been satisfactory.

Inoculation was attempted by Dieterichs with no satisfactory results. The experiments were repeated by Vix, who obtained results in the form of pneumonia, which was due in all probability to pyæmia. Nothing conclusive, however, was obtained until Dr. Willens of Hasselt, Belgium, instituted a series of experiments, the result of which led him to arrive at the following conclusions:—

“1. Pleuro-pneumonia is not contagious by inoculation of the blood or other matters taken from diseased animals and placed on healthy ones.

“2. That the blood and the serous and frothy liquid squeezed from the lungs of a diseased animal in the first stage of pleuro-pneumonia are the most suitable matters for inoculation.
3. The inoculation of the virus takes from ten days to a month before it manifests itself by symptoms.

4. The matter employed for the inoculation has, in general, no effect upon an animal previously inoculated or having had the disease.

5. The inoculated animal braves the epizootic influences with impunity, and fattens better and more rapidly than those in the same atmosphere with it that have not been inoculated.

6. The inoculation should be performed with prudence and circumspection, upon lean animals in preference; and towards the tenth day after the operation a saline purge may be given, and repeated if necessary.

7. By inoculating pleuro-pneumonia a new disease is produced; the affection of the lungs, with all its peculiar characters, is localised in some part on the exterior, but whether it occasions apparent morbid manifestations or not, the inoculated animal is preserved from pleuro-pneumonia.

8. The virus is of a specific nature; it does not always act as a virus. The bovine race alone is affected by its inoculation, since other animals of different races, inoculated in the same manner and with the same liquid, experience no ill effects.

Method of inoculation.—The virus is to be selected from the interlobular tissue of a lung in the first stage of a mild attack. The lung will then be found distended with a yellow semi-fluid exudate. All parts of the lung which present any appearance of dark red colour, and are consolidated, or which have the appearance of being gangrenous, should at all times be avoided. The selected portion of lung, after having been cut along the lymph spaces to allow the fluid to ooze out, is to be placed whilst warm in a strainer, over a clean stoneware or glass bowl, covered over by flannel or cloths, to keep in the warmth and to prevent dust, &c. gaining access. In a short time a quantity of clear yellow fluid will be obtained, which, if not required for immediate use, is to be enclosed in glass tubes, about four inches long, three-eighths of an inch in diameter, and, when filled, hermetically closed by a blow-pipe flame.

The tip of the tail is the spot which should be selected for inoculation, and a single drop of the virus is sufficient. It is better to inoculate on the upper than on the lower surface of the tip of the tail, removing the hair, and then slightly scarifying
the skin, the scarification being quite superficial. The point of
the tail is selected in preference to any other part, because it can
be easily amputated if gangrene occur.

In the most favourable instances, a slight heat and swelling
occurs round the inoculated spot in a period varying from a week
to two months; generally, however, the eruption manifests itself
from the ninth to the sixteenth day, accompanied by slight rigors,
loss of appetite, and slightly diminished secretion of milk. When
the operation has been properly performed, and the virus care-
fully selected, the effects are generally as above described; but
when the virus is putrid or badly selected, or, as sometimes
happens, some peculiarity exists in the inoculated animal, the
primary swelling is excessive, the tip of the tail becomes gan-
grenous, the animal suffers from a high state of fever; secondary
deposits occur at the root of the tail, around the anus, and in
the abdominal glands, and death occurs in a few days after the
inoculation.

The conclusions arrived at by the Belgian Commission with
regard to inoculation are as follows:—

"1. The inoculation of the liquid extracted from the lungs
of an animal affected with pleuro-pneumonia does not transmit
to healthy animals of the same species the same disease—at all
events so far as its seat is concerned.

"2. The appreciable phenomena which follow the inoculation
are those of local inflammation, which is circumscribed and slight
on a certain number of the animals inoculated; extensive and
diffuse, with general reaction proportioned to the local disease,
and complicated by gangrenous accidents, on another number
of the inoculated animals, so that even death may result.

"3. The inoculation of the liquid from the lungs of an animal
affected with pleuro-pneumonia exerts a preservative influence,
and invests the economy of the larger number of animals sub-
jected to its influence with an immunity which protects them
from the contagion of this malady during a period which has yet
to be determined."—(Gamgee.)

The losses sustained during the experiments of the Commis-
sion amounted to 11·11 per cent.; the number of animals on
which the operation was benignant was 61·11 per cent.; the pro-
portion in which there was gangrene and loss of a portion of the
tail was 27·77 per cent.; in twenty-one subjects the inflammation
was very severe, and complicated by gangrenous phenomena, causing the death of six; and lastly, the recoveries amounted to 88-85 per cent.

Following the method of Willens, Professor John Ganges introduced preventive inoculation into Edinburgh about 1837, but the casualties were very numerous, many animals dying from blood-poisoning induced by the operation; in fact the operation was condemned as being worse than the disease. In London it was condemned by Professor Simonds and others, and to the present time it finds no favour there.

Inoculation as practised by Mr. Rutherford, V.S., Edinburgh, and which has been attended with great success, is performed as follows:—

"On the occurrence of an outbreak I recommend the slaughter of such animals as are detectably affected, and, selecting one in the earlier stages of the disease, obtain from it the inoculating virus or lymph, the proper application of which gives protection to the healthy and unaffected that are left.

"Good lymph is the amber coloured fluid found in the interlobular tissues of the affected lung, under the pleuro-pulmonalis, and occasionally in the meshes of the exudate adherent to the ribs. I am strongly of opinion that no other material but this should be used, and that it should not be mixed with any antiseptic or weakening fluid, a practice which leads to unfavourable results, altering the character and destroying the vitality of the virus. If possible, I prefer to use lymph freshly obtained, and on no consideration use it if in the least degree decomposed or tainted.

"The part of the body to which I apply the lymph is the tip of the tail; for this reason, that in the event of the inoculative section terminating in or threatening gangrene, the part can be removed with a minimum of inconvenience to the animal, and also because that part of the body is well removed from the more important ones, to affect which with inoculation of a rapidly spreading character would in most cases be fatal to the animal, and of course to the success of the operation. I remove the hair of the under surface of the tail for about four or five inches from the tip upward, and with a pair of rewelling scissors make one transverse incision through the skin, about an inch from the tail point, and another about two or three inches higher up. A needle made for the purpose, with the eye at the point, is here pushed from the lower upwards through
the upper incision, and a few rapid movements made with it to enlarge the channel. This done, a piece of white thick worsted, previously well soaked in the lymph, is passed through the eye of the needle, which latter being withdrawn, the worsted is left in, pretty much in the way of a small serton, only that it is soaked with the specific virus of the disease. The operation takes about two minutes, and if done neatly, occasions little or no pain to speak of.

"The indications that successful inoculation is being effected begin to be manifested from the fourth to the seventh day. There are slight swelling, heat, tenderness, and erythema of the end of the tail, the hair stumps are raised, and the parts assume a brawny glistening appearance, and about the eighth, or from that to the twelfth day (occasionally later), exudation of lymph occurs of this character,—it is of the same appearance as that found in the lung, and if applied to another healthy animal not previously inoculated, nor the subject of pleuro, it will reproduce itself, and afford protection against the disease. I do not, however, consider it quite so reliable as lymph obtained in the ordinary way.

"Following the appearance of the exudate, there is a tendency in well-marked effective inoculations to gangrene of the inoculated part, and as this tendency is attended with the danger of its spreading, I have made it a practice to remove the tip of the tail above the operation, and cauterising with the hot iron the stump (just as is done when horses are docked). No ligatures are required before or after cutting, and the cut surface should bleed freely, and is a proof that no plugged vessels are left to lead to mischief. I am indebted to our friend Mr. C. Cunningham of Slateford for the suggestion to use the hot iron, and am satisfied its use has done much to reduce the casualty per-centague. If applied vigorously, it produces a dry covering on the stump impervious to air, and affording less chance to the recurrence of gangrene.

"I have noticed that in such cases as where the exudate makes its appearance early—say, for instance, by the seventh or eighth day—there is a great tendency for the inoculative action to spread rapidly, and even when the tail tip is removed early, there is in such cases a probability of the exudate occurring higher up. Where the exudate does not appear until the ninth, or from that to the twelfth day, I have found such cases give little or no trouble, and frequently I have not found it necessary to interfere with the process, which, from exudation, would either go on to drying of the exudate and decline of the inflammatory phenomena, or, a distinct line of demarcation being formed, the inoculated portion in process of time drops off.
"The time occupied by the operation I divide as follows:—

Period of development, . 1st to the 9th or 12th day;
" maturation, . 12th to the 21st day;
" decline, . from the 21st day;
and I have never known a casualty arise after this time.

"The percentage of casualty depends very much on the class of animal inoculated, and the care exercised by the operator in taking due precautions.

"Bullocks and young stock may be operated upon with little or no risk at all; the only precaution in their case being that they should be comfortably housed in the event of the weather being cold or very wet at the time of operation. Cows require more care, and should always be housed, summer or winter, and well protected from cold or draughts. I am in the habit, when I inoculate cows in cold weather, of clothing their bodies and putting straw on the byre rafters, thus keeping the byres as warm as on a hot summer day. Cold retards the occurrence of the exudate, and is apt to induce localization in the back, or in any part where the cold is blowing upon. For instance, a cow standing opposite an open door is apt to have localization of the exudate about the hips, and I have known cases where paralysis followed upon exposure of the whole body.

"No animal should be inoculated that is suffering from any illness, or about which there is any inflammatory action. Neglect of this would be followed by localization of the exudate in the inflamed part.

"Cows should not be inoculated until they are at least fourteen to eighteen days calved, and only then when they are known to be free of the effects of any accident attending upon parturition. I have inoculated cows within the fourteen days, and have reason to know it is not safe to do so. Cows in pregnancy should not be inoculated if beyond the seventh month, and then only where the circumstances necessitate the operation. A not uncommon casualty is meeting with exudate about the butt of the tail, extending either to the side of the hip or to the loose tissues surrounding the anus and vulva. The swelling is very apt to extend inwards, preventing the passage of feces and urine, and is accompanied with straining and great distress. It is the only dangerous form of secondary swelling, and in the first instance may be largely mitigated by simply dusting the parts frequently with flour, the application of warm coverings, a little linseed oil occasionally administered internally,—and above all, by the timely removal of such portion of the tail as may be dead, this being the common cause of the swelling. I have frequently removed the whole tail with success.
"I would point out that the attending operator, especially in the
case of milk cows, should give instructions that for three weeks the
animals should be very carefully gone about, not kicked or struck in
any way, and that no great change should be made in the feeding.
Care in this respect, and in keeping the animals always warm, is of
the highest importance, and in the success which follows the operator
has his reward. I visit them almost daily up till the seventeenth or
eighteenth day after the first week, for the purpose of watching that
they are going on favourably, and to act at once if they are not. The
results have been—the disease arrested in over a hundred outbreaks,
and my average mortality from the operation not over two per cent.

"The yield of milk is but trillingly interfered with."

"R. R."

Dr. Burdon Sanderson and other experimentalists recommend
the injection of the lymph into the venous system by means of a
small syringe, selecting the superficial aural vein for that purpose.
This method of inoculating, while inducing no local results, is said
to be quite as effective as that of inoculation of the tip of the tail.

Further investigations on the cultivation of virus, as recom-
mended by Pasteur with those of anthrax and fowl cholera, may
reveal the fact that an attenuated virus is quite as effective as
that removed from the pneumonic lung, and that successful
inoculation by direct injection into a vein may be performed
without inducing any local ill effects.

Intravenous injection has also been investigated by Professors
Thiernesse and Degive, who, having found that inoculation with
the lymph of pleuro-pneumonia in the cellular tissue of the
dewlap generally caused death, performed a series of experi-
ments, and concluded—

1st. That the injection of pleuro-pneumonic virus into the
veins is not at all dangerous, if care is taken that not a single
drop of this liquid falls into the cellular tissue.

2d. That this infusion possesses the same properties as
caudal inoculations,—that is to say, that it invests the animal
body with a real immunity.

Professors Thiernesse and Degive inject the virus into the
jugular, and recommend certain precautions to prevent all con-
tact between the virulent fluid and the cellular tissue. If,
however, the steel cannula be plunged into a vein, and then the
syringe adapted carefully, and care taken that all the fluid is
injected into the vein before withdrawing, first the syringe, then
the canula, there will be little or no danger of this occurring.

By the Contagious Diseases (Animals) Act, 1878, it is
decreed that all cattle suffering from pleuro-pneumonia are
to be immediately slaughtered. This is so far a movement in
the right direction, but I should like to see a modification to
the following effect:—1st. That all animals actually affected
should be slaughtered; 2d. That all animals suffering from the
disease in its incubative stage—that is to say, those in which
the fever can only be detected by the thermometer—should also
be slaughtered, and that all the unaffected cattle which are or
have been in contact with diseased ones should be inoculated.
In this way, I consider that the loss will be reduced to its
minimum, and that finally its occurrence in this country will
be prevented altogether.
CHAPTER XVIII.
CONTAGIOUS DISEASES—continued.

ECZEMA CONTAGIOSA.

**Synonyms.**—Eczema epizootica; epizootic aphtha; aphthous fever; foot-and-mouth disease; murrain; epidemic.

**Definition.**—A highly contagious and infectious febrile disease, associated with a vesicular eruption in the mouth, between the pedal digits, and around the coronets. In some cases the mouth only is affected, in others the feet may be the seat of the eruption, the membrane of the mouth remaining free. In milch cows it sometimes happens that a vesicular eruption occurs on the mammary gland, and within the lactiferous ducts; when such occurs, the milk, contaminated by the vesicular discharge, is rendered unfit for use, either as food for the human being or for the lower animals, as it may induce a vesicular eruption in the mouth, larynx, pharynx, and intestinal canal.

PATHOLOGY AND SYMPTOMS.

Unlike rinderpest and pleuro-pneumonia, which are almost confined to the ruminantia, contagious eczema affects cattle, sheep, pigs, dogs, poultry, and even human beings are subject to the influence of its virus. It is amongst horned cattle that we find the ravages of this disease to be most extensive, they seemingly being most susceptible to the influence of the contagious poison; sheep and goats, however, suffer very severely, and dogs, pigs, and poultry often die from it.

After a period of incubation, varying from twenty-four hours to three or four days, the invasion and progress of the disease are characterised by an elevation of temperature of from two to four
degrees; by the formation of vesicles, varying in size from that of a sixpence to that of half-a-crown, on the tongue, inside the lips, roof of the mouth, and sometimes on the udder; whilst smaller blisters make their appearance between the digits, and around the coronets and heels, and there is a discharge from the eyes and nose. The animal presents signs of uneasiness in the mouth, by constant movement of the lips, champing of the teeth, a flow of saliva from the mouth, and difficulty in masticating its food; the affection of the feet being indicated by some degree of lameness in the foot or feet affected. In a short time the epithelial and cutaneous structures enclosing the vesicles are separated and thrown off in more or less rounded patches, leaving raw surfaces (see Plate VI., p. 158), which are, however, speedily re-covered by epithelium. In some instances there is an entire separation of the hoofs from the feet.

The symptoms are undoubtedly due to the presence of a morbid poison in the animal economy, and are manifestations of the elimination or excretion of that poison, which evidently has some special affinity to the mucous and cutaneous structures of the several parts of the body which it invades. Eliminated by the feet and by the mouth, pastures very soon become impregnated with it, and hence we find that, owing to the great facility by which it is thus spread over a wide district of country, it appears to be the most infectious of maladies. Beyond question the virus of eczema is conveyed from field to field, from parish to parish, from county to county, by small game, vermin, and dogs; and looking to this fact, we can account for the sometimes mysterious outbreak of the disease in places and districts into which no fresh cattle have been admitted. This frequently unaccountable appearance of the foot-and-mouth disease has led to the belief that it is of spontaneous origin; some believing that, although originating spontaneously, it is propagated by contagion; others that it originates in all cases independently of contagion, and that it is due to climatic or atmospheric causes, exposure, and the debilitating effects of long journeys by land or sea. It is very true that increased susceptibility to the disease is induced by any debilitating cause, but neither age, condition, management, climate, temperature, nor any common cause of disease seems to exert any modifying influence. No extremity of privation, nor the continued action of ordinary causes, is
ECZEMA CONTAGIOSA.

capable of inducing it; and one reason for the indifference which has been shown in respect to its ravages is to be found in the belief in its spontaneous origin, an idea which arises out of the observations of its frequently unaccountable appearance in isolated places.—(Professor Brown on Mouth and Foot Complaint.)

It was at one time believed that an animal which had once suffered from eczema contagiosa was guarded against another attack. This, however, is a fallacy; and it is now generally believed that an animal is only once attacked during a season. As a general rule this may be said to be the case, and consequently a herd which has gone through the disease early in the season—let that be the spring or autumn, the periods when, in consequence of the increased movements of cattle from place to place, the disease is most rife—is considered more valuable to the purchaser, and worth more money in the market. This rule is, however, liable to many exceptions, and it is by no means impossible for the same animal to suffer from two, three, or even four attacks during a period of a few months.

Some observers have thought that the contagium was contained or existed in the form of a vegetable parasite—fungus; whilst others, speculating as to its source of origin, have advanced the idea that it is due to the development of organic germs having independent movements—in fact to living particles of animal matter. These are, however, speculations which cannot be confirmed by examination with high microscopic powers; they therefore fall to the ground. Microscopic examinations of the blood, saliva, tears, and the contents of the vesicles, have failed to detect any substance to the presence of which the disease might be ascribed. The blood corpuscles are very oftenstellate or star-like in form, and rapidly change to their natural circular shape; there is, however, no speciality in this as regards the blood of cattle, as the same thing occurs in splenic apoplexy, rinderpest, and even when an animal is apparently in a healthy condition. Professor Brown attaches some importance to the presence of vibriones, bacteria, and monads, which are found in the discharge from the eyes, saliva, and the contents of the vesicles. The milk also contains these bodies, and upon this head Professor Brown is very clear and distinct. He says—"Milk from cows affected with foot-and-mouth disease acts energetically upon young animals to which it is given warm.
Calves occasionally die quite suddenly after sucking cows affected with the malady; and fatal effects have followed the administration of the milk to young pigs. It has been alleged that there is not any direct evidence of injurious consequences arising from the consumption of the milk by human beings; but it must be remembered that the fluid is very rarely taken immediately from the cow, and still more rarely in an undiluted form, and it may be not altogether an unfortunate circumstance that the decrease of the secretion during the prevalence of the disease necessitates a large admixture of water in order to keep up the quantity which is required for daily consumption.

"In the early stage of the disease the milk presents few abnormal characteristics, the specific gravity falls to 1024, and the milk corpuscles are always found to be arranged in clusters. Minute moving specks are also seen under the quarter-inch objective, and those under the 5Xth are resolved into bacteria and spherical bodies.

"When the disease is fully developed, about the third day from the first appearance of vesicles, the milk invariably contains morbid products of a very pronounced character, viz., large granular masses of a brownish yellow colour, numerous pus-like bodies, bacteria, vibriones, moving spherical bodies, and a few milk corpuscles. It is particularly worthy of remark that these morbid elements were found in specimens of milk which in their physical character presented no appreciable peculiarity.

"In some specimens which were viewed with the micrometer eye-piece the milk corpuscles varied in size from \( \frac{1}{10000} \)th to \( \frac{1}{1000} \)th of an inch in diameter, and the granular masses from \( \frac{1}{1000} \)th to \( \frac{1}{10000} \)th of an inch. Milk from animals affected with cattle plague, and also with pleuro-pneumonia, was also found to contain an abundant quantity of the granular masses and pus-like bodies; and in cases of cattle plague similar elements were distinguished in the curdy exudation which existed in the mucous membrane of the mouth, pharynx, trachea, and bronchial tubes.

"Examples of milk taken from animals in different stages of foot-and-mouth disease afforded very interesting results. At the commencement the specific gravity fell to 1024-5, and continued to range between the two numbers until the animal was convalescent, when it rose to 1026-7, which standard was not exceeded for two months after recovery.
"The granular masses and pus corpuscles decreased in number as the affection subsided; but in all the specimens examined after the animals had recovered, they were found scattered here and there among the milk corpuscles, and even in specimens which were examined a month after recovery they were detected. The granular masses were not found in milk from the same animals two months after recovery; but even in these specimens a few pus-like corpuscles were present.

"Two examples of milk taken from cows on the fourth day of the disease were found to be highly charged with granular masses; the milk, however, was remarkably rich in quality, having a specific gravity of 1034, and yielding a large proportion of cream. Diminution of the quantity of milk is invariably observed during the progress of any febrile disease, and in foot-and-mouth complaint the loss is sometimes considerable.

"Cows, when suffering from the worst form of disease, lose nearly all their milk; but when the attack is mild in character, the decrease will not be more than one-third of the usual yield. The average loss in a large dairy while the disease is going through the sheds will vary from one-third to two-thirds, according to the number of severe cases. As all the milk obtained is mixed, the worst milk will be to some extent modified by the addition of that which is less highly charged with morbid elements, and the whole is further diluted by the addition of water, which, judging from some specimens obtained from an establishment where the disease was known to exist among the cows, is sometimes added to the extent of 40 per cent. Boiling the milk has been recommended for the purpose of preventing or lessening its injurious action; but, as a matter of fact, it may be stated that boiling does not alter the appearance of the morbid elements, nor does it arrest the movements of bacteria in the fluid."

In ordinary cases of eczema the symptoms are not very severe, and provided the feet are not seriously implicated, the animals recover in about a week from the first manifestation of the febrile symptoms. In many instances, particularly if the weather be cold and the cattle exposed, a hoarse tracheal cough is present, with much discharge from the trachea and bronchial tubes, whilst in aggravated cases the mucous membrane of the intestinal canal is very seriously involved, and when vesicles appear
at the anus, it is fair to presume that vesication exists along the whole alimentary track; and post mortem examinations of such reveal the presence of much inflammation of the intestinal mucous membrane, patches of demudation here and there, more especially in the fourth stomach, giving the disease very much of the characteristic appearance found in cattle plague, to which disease it is to some extent allied.

It is when the feet are much affected that the loss to the stock-owner becomes great, for not only does the animal lose condition from the disease, but also from inability to roam about its pasture in search of food. Such cases should at once be comfortably housed, provided with proper aliment, and have the feet properly treated.

In sheep, goats, and pigs, the feet are the principal parts affected, the vesicles occurring between the digits and around the coronets.¹

During the summer of 1872 eczema contagiosum assumed a very malignant character, especially in some herds of Iceland cattle brought to Leith and Edinburgh, the ordinary symptoms being complicated with swelling of the legs and other parts of the body, the swelling when opened discharging a very fetid fluid. In all there was great prostration of strength, and many cases terminated fatally.

The loss from foot-and-mouth disease to the dairyman, from the diminished secretion of milk, and to the owner of cattle nearly fit for the butcher, is very great. I do not think £4 a head too high an average; but when it is confined to lean or store cattle, provided the attack is mild, the loss of condition is quite ephemeral, and can scarcely be accounted a loss at all, for such animals appear to make flesh much faster after than prior to an attack of the disease.

The flesh of cattle which have been slaughtered while suffering from the disease exhibits in many instances the presence of numerous worm-like bodies called "psorosperms"² lying loose amongst the fibres. The true nature of these bodies is not yet

¹ For distinguishing character of foot-and-mouth disease and foot-rot in sheep, see Principles and Practice of Veterinary Surgery.

² Psorosperms are found in cysts—parasitic in vertebrates, and develop into forms ofgregarism.—(Huxley.) Ballbian believes them to belong to the vegetable kingdom.
quite known. They are evidently quite harmless, and are present in other diseases, and sometimes when the animal has been slaughtered whilst apparently in the best of health.

As sequelae to eczema contagiosa, the following alterations of structure have been observed, namely, swelling of the joints, open joints, with sloughing of interdigital substance, gangrene of a whole foot, marasmus, and disease of the bones.

**TREATMENT OF ECZEMA CONTAGIOSA.**

Mild cases require little medical treatment, foot-and-mouth disease being one of that kind which, running through a definite course, terminates in recovery. Whilst the mouth is very sore, all that the animal requires is a plentiful supply of cold water: if the fever be high, the water may contain an ounce of nitrate of potash dissolved in each bucketful. As a rule, however, even this is unnecessary. The food should be soft and easy of mastication—bran mashes, pulped roots, or grass. The feet must be looked to, and if suppuration be detected, with separation of some parts of the horn, the detached horn is to be removed, and the exposed sensitive surfaces dressed with a mild astringent, such as a solution of acetate of lead, containing a small medicum of carbolic acid. What I usually prescribe is an ounce of the concentrated solution of pure carbolic acid—one part acid to sixteen hot water—to twelve of the white lotion. Pledgets of tow dipped in this lotion are to be bound to the foot by a bandage. This simple expedient, so generally neglected, will often prevent a lameness of many weeks’ or even months’ duration; for suppuration, once established to any great extent in the sensitive structures of the foot, causes violent pain, increases the inflammation, and induces the process of sloughing. Some writers recommend a variety of remedies both to the mouth and feet. My experience leads me to the conclusion that, except carefully washing the feet, the less medical interference the better.

Now and then cases will be marked by extreme prostration of strength, entire loss of appetite, inability to stand from weakness as well as from the lameness; such ought to be more actively treated, and stimulants, such as whisky, brandy, or spirits of nitrous ether, administered internally, and the feet washed repeatedly with cold water, and kept cool with wet
matter, taken from a pock upon the body of a man who had died of small-pox, into a cow's udder, and subsequently vaccinated some fifty persons with the matter derived from the cow. Most of those so inoculated were attacked, not with vaccinia but with variola (small-pox), and three died. It is difficult to reconcile such a wide difference in the results of experiments seemingly carefully performed, but I am not prepared to admit that the experiments of Chauveau and those of Martin have satisfactorily proved that those of others were wrong. In 1836 Dr. Basil Thiele of Kasan, in South Russia, inoculated some cows on the udder with the virus of human small-pox, the result being the production of vesicles bearing all the characteristics of the true vaccine vesicle. The lymph so produced from the variolation of the cows continued to retain the specific properties of variola vaccine throughout seventy-five successive transmissions to the human body; and it is not stated that it had lost its specificity after so many transmissions.

In the face of such conclusive evidence, I think we are justified in concluding that in the experiments made by Chauveau, the virus, granting that it was properly selected, had not undergone that alteration during its transmission through the bodies of the inoculated animals which modifies and mitigates its virulence under ordinary circumstances, and that the virus selected by Martin from a fatal case of small-pox was not proper for an experiment where human life was at stake.

Many experiments might be quoted (Ceely, Thiele, and others) to prove that great uncertainty and difficulty often attend the attempts to transfer the virus of variola from one animal to another; that when variolous disease affects the lower animals in a malignant form, it is capable of producing by inoculation a disease of similar severity in man, and that marked improvement sometimes takes place in the energy and in the quality of the virus by subsequent removes or inoculations in animals of the same kind, after the variolous virus had been successfully implanted in one of them; it seems to become less acid, less virulent, and to acquire increased specific activity; capable of inducing more pronounced and perfect development of vesicles, with milder and less dangerous general symptoms.

Variola vaccine has been transmitted back to the cow from
man (retro-vaccination). By this process good human lymph loses some of its activity, for, according to Mr. Ceely, the phenomena in man, after vaccination with this retransmitted lymph, appears later, smaller vesicles are produced, but ultimately, after successive inoculations on man, it regains its activity.

The disease vulgarly termed "grease" in the horse, believed by Jenner to be the origin of variola, has nothing to do with small-pox or cow-pox; but it is placed beyond a doubt that the horse is subject to a true equine pox, and that it is transmissible to the cow by inoculation and cohabitation. It is stated that the equine pox occurs as an epizootic when small-pox is epidemic. When small-pox was raging in Edinburgh in 1872, I saw one case of what I considered genuine equine pox. The animal (a mare) presented signs of fever, had a slight cough, loss of appetite, with costive bowels for eight or ten days before any skin disease was observed. She was treated for a common cold, with fever; but at the end of the time mentioned small pimples were observed on various parts of her body, more particularly about the shoulders and back. At first these pimples were very numerous, small, and pointed; the great majority of them, however, withered, and a small scab fell off, leaving the skin bare of hair. About a dozen on each side of the shoulders and upon the back increased in size, became vesicular, and afterwards pustular. These eruptions had very much of the character of those seen in cow-pox, namely, pimples increasing in size from a point to that of a horse-bean, becoming vesicles in three or four days, and then pustules, depressed in their centres. In about ten days, or eighteen after the first manifestation of illness, dark, thick, solid scabs formed on the sites of the pustules. These scabs did not all fall off until fully a month had elapsed, and the hair was not completely restored in two months afterwards, when I lost sight of her. Jenner, Sacchetti, and others, have used equine lymph for the purpose of vaccination, and human small-pox has been transmitted through the horse to the cow, and so to the child in the form of cow-pox.

It has not been determined whether the small-pox poison originated in man, the cow, or the horse; whether man had the disease communicated to him from the lower animals, or whether horses and cows had it from man. The origin will most probably for ever remain a mystery, and we must be content with the
knowledge that, through the keen penetration of Jenner, the disease directly communicated by vaccination from the lower to the higher animal has proved a blessing to millions of the human race.

There are many forms of eruption in the udder of the cow, which are sometimes confounded with those of variola; but those of variola have certain characteristics which distinguish them from all other, or so-called spurious, forms of the disease. The local symptoms of the true variola are heat, swelling, and tenderness of the teats for three or four days, followed by irregular pimply hardness of the skin, more particularly about the base of the teats. The pimples may sometimes be felt in five days after communication: they assume a red hue when about the size of a pea, are very painful and hard, gradually increase in size, and in other three or four days attain that of a horse-bean, assuming a circular form on the udder, and an oblong on the teats. They rise in the centre, become more or less pointed (acuminated), containing at first a clear, and ultimately a turbid fluid. If the vesicles are broken, troublesome sores supervene, the discharge from which will communicate the disease to the milker, if he is not already protected by previous vaccination. The vesicles, if not broken, become depressed in their centres, and have an indurated margin, around the circumference of which the skin denotes active inflammation by a circle of redness, acquiring their maximum size about the tenth day, and are then pustular; and as the pustules dry, dark brown or black solid scabs or crusts form upon the surfaces. Some of these scabs may be seen semi-detached, others entirely so, exposing a raw surface, with a slight central slough. Vesicles, pustules, and scabs may be witnessed on the same teat at one and the same time, indicating the formation of new crops of vesicles at different periods. The crusts, if left undisturbed, gradually become thicker, darker, and more compact until about the fourteenth day, and spontaneously separate about the end of three weeks, leaving shallow, smooth, oval, or circular pits of a pale rose colour, with some traces of surrounding induration.

The depression in the pocks is accounted for in various ways. Dr. Petzholdt thinks it is caused by the ducts of the cutaneous glands, which are ruptured as the pustules fill with pus and mature, but which, in the early period of the eruption, bind
down the cuticle to the cutaneous glands, thus producing the pit or umbilicus.

Dr. Gustav. Simon differs from the above opinion, and says that "variolous pustules are not always constituted alike. In many cases, where a central depression clearly existed, the epidermis was entirely raised from the subjacent cutis; and only at the spot corresponding with the umbilicus were both membranes united by a thin, whitish cord, which, as the microscope evidently showed, was a hair sac. The presence of a hair sac is not, however, essential to the production of an umbilicus, and a remarkable peculiarity, first noticed by Rayer, characterises the variolous vesicle in those parts of the body where neither hair sacs nor sebaceous follicles exist. Rayer found, on removing the epidermic cap of the vesicle, and wiping off the fluid collected beneath, that a little elevation existed in the centre of the denuded corium, whilst the circumference was visibly depressed below the level of the neighbouring healthy cutis. These elevations were found by Dr. Simon, who examined them microscopically, to consist of a file of papillae of normal or nearly normal size and condition, while the depressed margin is paved with papillae bent down or flattened. The explanation is simple. At the centre of the vesicle an organic connection (from some yet unexplained cause) exists between the cutis and cuticle, and at this point no fluid is effused; but around this centre, exudation of fluid occurs without impediment, and tends to force the cutis and cuticle asunder."—(British and Foreign Medico-Chirurgical Review, vol. iii.)

About the ninth day of the vaccine disease a purely vesicular eruption makes its appearance upon the udder. Within twenty-four hours the vesicles contain a pellucid serous fluid. On the following day the fluid becomes turbid, the cuticle collapses or bursts, and a thin, brittle, flimsy crust forms, and speedily falls off. Successive crops continue to form and dessicate for three or four weeks.

It is difficult to trace the origin of an outbreak of variola vaccinæ in a herd of cattle. Outbreaks of it seem to follow similar inexplicable paths to those which characterise other contagious diseases. Cases spring up now and then which appear to be solitary, and cannot be traced to a cause. At other times it seems to be epizootic, and prevails at several farms at the same
time. Unlike, however, the other contagious diseases of horned cattle, and unlike variola ovina, it is a disease which seldom or never proves fatal in this country. In some instances, the constitutional disturbance is rather severe, the mucous membranes being particularly prone to participate; the mouth becomes sore, and there is drizzling of saliva.

In hot climates the symptoms are succeeded by abdominal pains, profuse diarrhoea, rapid wasting of flesh, and sometimes death; but in temperate climes the general symptoms are slight diminution in the secretion of milk, with but little or no loss of appetite.

The contagium of variola in the cow is fixed and transmissible by actual contact only. It has been shown by Chauveau that the virus introduced into the digestive organs produces the disease as surely as when injected into the blood-vessels or implanted in the skin. The same authority states that the virus is contained in the corpuscles, and not in the serum or fluid of the lymph.

When once the disease breaks out in a dairy, it is apt to spread to the whole herd, unless precautions be taken against its diffusion, by segregation of all affected animals and the employment of separate attendants, particular care being at all times taken that the milker of an affected cow shall not touch a healthy one. The milk should be drawn off with the teat syphon, and, if the mammary gland becomes much inflamed, fomentations may be necessary, with other treatment recommended for "mammitis" (see Principles and Practice of Veterinary Surgery); but in all ordinary cases of the disease non-interference is to be strictly observed.
CHAPTER XX.

CONTAGIOUS DISEASES—continued.

VARIOLA OVINÆ (SHEEP-POX).

Synonyms.—Clave ou Clavelé (F.); Schafpocken, Schafpoche, and Schafplatten (G.).

Definition.—A contagious and infectious eruptive disease, analogous to small-pox and cow-pox; runs a definite course, and occurs but once, as a rule, in the same animal. It is divided into two forms:—1st. A malignant, virulent, or confluent form; and 2nd. A benign or discrete form. The malignant form never produces vesicles; the sheep lose their eyes; their wool falls off, the skin cracks in a zig-zag manner, and the nostrils become filled with a fetid discharge. In the benign form, genuine vesicles appear, which, after the scabs fall, leave pits in the skin, on which the wool never grows again. According to Professor Simonds the disease is not communicable to the cow or to children. Saccho, however, states that ovination is protective against small-pox.

HISTORY.

Sheep-pox is said by Mr. Fleming to have appeared as an epizootic in England about a.d. 1277, but that it was well known in Britain more than two hundred years previous to 1275, and was called the Rot. The term variola had, however, been made use of in 569 (Animal Plagues, 1875). But in more modern times sheep-pox was unknown in this country until 1847, when it broke out on a farm at Datchett, near Windsor, where it was introduced by fifty-six merino sheep, brought to this country in the ship “Trident,” from Tönning, in Denmark.

Professor Simonds, in his treatise on Variola Ovinæ, says of
these sheep—"When disembarked they appeared to be in health, and were sold by the salesman to whom, with other sheep, they were consigned. We have not succeeded in tracing the subsequent distribution of each separate lot of this cargo, but we are assured that many of the animals continue well. It is, therefore, evident that in this particular instance the malady was imported from Denmark; but this unfortunately did not prove to be a solitary case of its introduction.

"Within a day or two of the arrival of the 'Trident,' the 'Mountaineer' and the 'Princess Royal' came into port, each vessel having on board a number of merino sheep brought from Hamburg. . . . . Some of these sheep—507 brought by the 'Princess Royal'—were sold to butchers; others to farmers, as 'stock sheep.' The latter were bought in several quantities on 26th July by Mr. B. Weall, of Woodhall, Pinner; Mr. Goodchild of Kingsbury; Mr. Pittman of the same place; and Mr. Choke of Barking. These purchased by the two last-named gentlemen are said to have continued in health ever since. Mr. Goodchild's sheep, however, showed symptoms of the disease very shortly after arriving at his farm, their illness being attributed to his having had them dipped or washed, for its true nature was not suspected. That portion of the cargo of the 'Princess Royal' which was purchased by Mr. Weall consisted of 80 merinos; and on the same day he bought 166 other sheep of the merino breed that had arrived by the 'Mountaineer.' These two lots were placed together, and subsequently, being sent to Pinner, were equally divided between Mr. Weall and his brother. In each moiety the disease showed itself, being first observed among the 80 sheep about ten days after their purchase, and from them it rapidly extended to others. Out of those belonging to Mr. B. Weall, 20 died in the acute stage of the malady, 27 more were sacrificed, and the residue was disposed of at a low price."

"We examined Mr. B. Weall's flock on the 7th of September, and found two of the sheep in the earliest stage of the malady; but most of them were recovering."—(Simonds on Variola Orinæ.)

The outbreak of 1847 committed great ravages in Middlesex, Surrey, Norfolk, Cambridgeshire, Suffolk, and Hampshire, and continued during 1847, 1848, 1849, and 1850; the losses from
it were also severe in 1852, and more so in 1853, at which time the practice of slaughtering sheep in or near London put an end to the disease until 1862, when it broke out at Allington, in Wiltshire. This outbreak was supposed to be of spontaneous origin, as it could not be distinctly traced to foreign sheep. Mr. Gamgee visited the district at the time, and made many observations, from which he came to the conclusion that "the district turns out to be one not unfrequently visited by contagious disorders. . . . The district is traversed in all directions by driftways, so that drovers can pasture their sheep on the downs for days, and go from Bristol to London with the payment of a single toll. There are some notorious dealers who have no farm or down on which to keep their flocks. They pick up odd animals at a low price here and there, and drive over the downs, where they sleep, and move gently backwards and forwards on the pretext of travelling, but in reality getting food for their flocks. Many instances have occurred of the spread of contagious disorders, such as scab, the foot-and-mouth disease, foot-rot, &c., from these infected flocks passing over the downs along the Wans Dyke." The disease is not readily transmissible to other animals, but it appears that goats, pigs, hares, rabbits, and dogs are amenable to it.

These observations of Mr. Gamgee, along with the fact that sheep-pox is one of those diseases which never occur spontaneously in this country, are to my mind quite sufficient to account for the Wiltshire outbreak.

The early history of sheep-pox on the Continent of Europe, in some parts of which it is very prevalent, is very confused; it is certain, however, that it was introduced into Western Europe by diseased animals brought across the Russian frontier into Poland, Hungary, Prussia, Pomerania, &c. Rammazini states that the malignant affection amongst cattle and sheep which prevailed in 1514, 1599, and 1691 was small-pox. From his description it is very probable that the disease of 1691, which chiefly attacked sheep, was in reality variola ovina, inasmuch as it was characterised by pustules similar in form, colour, and in the manner in which they went off. When they had died off after the suppuration, they left a black scar, like that which remains after the small-pox.

Professor Simonds instituted various experiments which prove
that variola ovine is inoculable, contagious, and infectious, and that its incubative stage varies from seven to thirteen days when communicated by inoculation, and from nine to twelve days in natural cases.

Like the poison of cattle plague, that of sheep-pox is both volatile and fixed, existing in the blood, the tissues, secretions, and emanations, and may be carried from place to place in the clothes of attendants, in fodder, wool, skins, and particularly by dogs. Mr. Chas. Percivall informed Mr. Gangee that he had seen a dog (Mr. Stephen Neste's) suffering from symptoms of disease identical with those of variola ovine, and there could be no doubt but that the dog contracted the disease from affected sheep (Domestic Animals); and it is pretty well demonstrated that a healthy flock is not secure from the disease at the distance of a quarter of a mile from affected sheep. Upon this head Continental writers are very clear, and they point out the danger of driving a healthy flock on the same road which shortly before has been travelled over by a diseased one. Chauveau has shown that the virus is a hundred times more infective, that the matter contains in an equal quantity thirty times the number of corpuscles, and is more active than that of vaccina. He has also shown that if vaccine matter be diluted with fifty times its weight of water, it propagates itself when inoculated with great uncertainty, while ovine matter may be diluted 1500 times before its virulence is appreciably affected.

The virus retains its vitality, when protected from the air, for a very considerable period, but is destroyed by the influence of air, heavy dews or rain, sunlight, a temperature of 122° F. frost, and disinfectants, such as chlorine, permanganate of potash, and ozone, as well as by putrefaction, and if the wounds be suppuring, the matter from them will not infect.

PATHOLOGY AND SYMPTOMS.

As already stated, the period of incubation varies from about the seventh to the thirteenth day, during which time there are no symptoms observable to a non-professional person. Like all specific fevers, however, there is an increase in the temperature of the animal body for some time prior to the outward manifestation of the disease. In thirty-six to forty-eight hours after the first manifestation of the disease, the temperature rises to
105°, or even as high as 107° or 108°, but in the benign form it diminishes at the commencement of the eruption. In the malignant it is slower and later in diminishing, more irregular, and increases when suppuration occurs, becoming normal at the period of desiccation. A careful observance of the temperature is of great importance, in order that affected sheep may be removed from the flock before any of the ordinary signs of the malady can be detected, and before the disease becomes infectious. By carefully watching and examining their flocks, some farmers have been able to arrest the spread of the malady, and the course they have adopted has been that of segregating the diseased ones when the slightest rash made its appearance upon them. Mr. Charles Fielder of Sparsholt, near Winchester, says—"I employed two men to turn every sheep I had on my farm, and minutely inspect every one of them; and if they saw the slightest appearance of any rash, or a single pustule showed itself between the inside of the shoulder and the breast, where the skin of the sheep generally looks white and clean, and where it was sure to show itself first, I had it immediately taken away, putting the whole of the diseased together in one large field in the middle of my farm, at a distance from any road, as a protection to my neighbours. I followed the same course every morning, by having all my sheep turned and closely inspected, not looking to the trouble and expense, as I felt in my own mind that it was the only remedy I had to stop the infection; as I calculated, if I could only find out those sheep which had taken the disease and were breeding it, before it became infectious to others, I should be able to arrest its progress. Fortunately I was right in my calculations, for they daily decreased in numbers, although they still kept faltering for a fortnight or three weeks from the time I began turning them (particularly in one flock where the Spanish sheep had been), before it, as I hoped, ceased altogether, as I have not found a diseased one for some time past."—(From the Farmer's Magazine, vol. xvi., page 524, quoted by Professor Simonds.) If separating the diseased from the healthy sheep after the first symptoms of the malady are discernible by an ordinary observer has so far been sufficient to arrest its spread, it can easily be understood that removal prior to the appearance of the rash will yet prove more satisfactory.

Symptoms.—The first appreciable signs of the disease, after the
termination of the incubative stage, are recognisable "by the existence of papulae or nodules deeply imbedded in the dermis, having a florid red aspect. These show a preference for some parts of the integument, and are usually to be first detected on the inner side of the arms and thighs, and on the cheeks and lips, where the animal has a hairy and not a woolly covering. Other portions of the body are often simultaneously attacked, as the prepuce, labia, anus, and under surface of the tail—parts which are perfectly nude."—(Simonds.)

In some cases there will be a diffused redness of the skin, in patches of various sizes, prior to the formation of the papulae. Professor Simonds says that in inoculated cases this is so well marked that it constitutes a disease of the skin, analogous to rosacea variolosa of the human subject, and establishes another similarity between these maladies.

During the papular stage the skin has a flea-bitten appearance, the eruption being at first in the form of small red points; these gradually enlarge, often uniting one with another. Professor Simonds considers that three days may be regarded as the period of population, and that it is generally longer in confluent than in the distinct form of the disease. The disappearance of the papulated eruption, the disease afterwards lying dormant in the system for three weeks and then breaking out, as described by Hutrel d’Arboval, was not witnessed by Professor Simonds.

Concomitant with the appearance of the rash, febrile symptoms are manifested, the animal becomes dull, with blood-shot eyes, is thirsty in all cases where the eruption is extensive, and the papulae confluent. Where the eruption is distinct the febrile symptoms are much milder. Continental writers state that the outward signs of fever precede the eruption: the experience of Professor Simonds and others in this country does not confirm this, for in all cases seen by Professor Simonds the eruption preceded the constitutional disorder.

"The red papulae gradually enlarge in size, then become elevated and transparent in their centres. The papula is now a vesicle containing a liquid at first transparent and then turbid. Many of the vesicles are very small, and if punctured yield no fluid. The duration of the vesicular stage differs to some degree, and it has been observed that many of the papulae disappear without vesicles being produced. The ovine vesicle is flat on its
surface; and in this particular it forms a contrast both with the
vaccine vesicle of the cow and the variolous of man. The
serosity of the vesicles, first clear, becomes milky, turbid, less
serous, and straw coloured, and ultimately by drying hardens
into a crust, and is cast off with the epidermis."—(Simonds.)

"Both Professor Simonds and Mr. Ceely are of opinion that the
term *pustule* should not be applied to the eruption, except, as
Mr. Simonds says, in the latter stages of extreme and protracted
cases, where pus is in reality formed, and is succeeded by the
ulcerative process.

"The period of desquamation or dessication depends on the
extent of the original eruption, and also on its being distinct or
confluent. It is likewise governed by the amount of inflamma-
tory action which existed in the dermis, and is always protracted
when suppuration has taken place."—(Simonds.)

The vesicles, scab, and crusts are liable to be injured in various
ways, but more particularly by the sheep scratching themselves,
and this interferes materially with the process of healing, and
does not always cause irregularity in the duration of the malady.
"In natural cases, even when mild," says Professor Simonds,
"and when no cause retards their completion, a month, reckon-
ing from the period at which the animal was first exposed to the
contagion, usually passes before it is restored to health.

"The following summary of the gradations of the malady may
be accepted as sufficiently accurate for practical purposes:—The
first ten or eleven days are those of incubation; the twelfth and
thirteenth of invasion; the fourteenth, fifteenth, and sixteenth
of *papulation*; the seventeenth, eighteenth, and nineteenth of
*vesication*; the twentieth, twenty-first, and twenty-second of
*suppuration*; and the twenty-third to twenty-eighth of *dessication*
and separation of the crusts."—(Simonds on *Variola Ovina*.)

The same authority says that the constitutional symptoms,
especially those which indicate the greatest danger, "are dejec-
tion, the head being held low; the infected animals separate
from their fellows; mostly lie down in a corner of the field; the
ears are pendent; the breathing quick and short; the eyelids
are swollen, and tears trickle down the face; the conjunctiva
varies in shade from a bright scarlet to a modena red; a mucus
discharge flows from the nostrils, and increases in viscosity
as the disease advances, often becoming sanguineous in the
latter stages; yellowish spots may likewise be seen scattered here and there on the pituitary membrane; the pulse early gives evidence of febrile excitement; at first it is quickened and somewhat increased in force, numbering about ninety-five beats in a minute; later on it becomes tremulous and indistinct, even over the region of the heart; rumination is suspended, and all food refused; but the patients show a great disposition to take water, and also to lick earth, which, mingling with the mucus of the nose, assists in clogging the nasal openings, and renders the respiration more difficult. The alvine evacuations are but little changed in the majority of cases; in some, however, diarrhœa succeeds to a torpid condition of the bowels, and hastens the fatal termination; the temperature of the body is unequal, the feet and ears being generally cold, while the skin elsewhere is hot.

"These symptoms, more or less modified, are present from the commencement of the eruption, and seldom abate until the papular stage gives place to the vesicular, when the animals usually experience a relief. In all natural cases, the constitutional disturbance is great, and makes the probable termination of the attack doubtful, which is also rendered more uncertain when the confluent form of variola prevails; for the type of the disease, as elsewhere stated, governs to a considerable extent the amount of the fatality.

"Not only is the prognosis unfavourable in confluent variola, but it is equally so if the fever continues unabated, which is certain to be associated with an augmentation of the patient's sufferings. The breathing now becomes rapid and painful; the inspirations frequently, but more often the expirations, are accompanied with a moan; frothy saliva is discharged from the mouth; the exhalations are fetid; the wool separates from the skin on the application of the slightest force; ulcerations of the conjunctival membrane occasionally result; and sometimes the internal structures of the eye give evidence of disorganisation; the animal shrinks from the touch; the pulse gets more and more indistinct; great prostration of all the vital powers succeeds, and death closes the painful scene."

The per-centlage of mortality arising from variola ovina varies considerably; very often half the sheep which are attacked succumb to the disease, and it is not unusual for nearly the whole
flock to be swept away. Mr. Gamgee states that in one outbreak "the losses on 3811 sheep were 221 before inoculation had been practised, and the loss since has amounted to 537, or a total of 758 on 3811, viz., very nearly 20 (19.89) per cent., whereas in 1310 not inoculated the loss amounted to 21 sheep, or 1.6 per cent."

It is evident that Mr. Gamgee intends the reader to understand that the small mortality in the 1310 was due to the precaution of separating the diseased from the healthy animals during the earlier stage of the malady.

**POST MORTEM APPEARANCES.**

The post mortem appearances of small-pox are as follows:—Body swollen, and exhaling a fetid odour; the eyes and nose closed with dry discharges; the mucous membranes of the mouth, nose, pharynx, oesophagus, larynx, bronchi, and rumen are covered with light copper-coloured varic or nodules, and occasionally small ulcers are seen on the epiglottis and other parts of the larynx. The lymphatic glands in various parts of the body are enlarged, and marked with red spots. The subcutaneous tissues are engorged with blood, and covered with solid red nodules, whilst purulent formations exist beneath the confluent papulae. The acreral tissue of the face and extremities is often filled with effusion, and the skin itself is in some parts red, in others of a blackish hue, and the wool, if not already detached during life by the animal scratching itself, easily comes off.

**PREVENTION AND TREATMENT.**

The prevention of the disease in this country depends upon the exclusion of animals from infected countries. The incubative stage being of such a duration, affected animals may easily pass the examination of the most careful inspector, no signs of illness being manifested during this stage.

If, however, variola should appear in a flock, the best way of dealing with it is that recommended by Mr. Fielder (see page 201), namely, the separation of all diseased sheep during the earliest

---

2 In Mr. Gamgee's book it says very nearly 10 (19.89) per cent.; the figure 10 is evidently a mistake.
stage of the disease; and pastures, roads, and other places frequented by the diseased animals should be avoided until heavy rains have destroyed the contagium.

Inoculation or ovination is recommended by very high authorities. In this country, however, the experiment has not proved at all satisfactory. French veterinarians speak highly of ovination: thus, at the Alfort Veterinary School the mortality was only at the rate of 1 in 400 after ovination. Professor Simonds says our experiments are too limited to suggest correct conclusions, and they have shown a result so different, that, were we to found an opinion on the merits of ovination on them alone, it would not be in favour of the practice. The deaths have been at the rate of 20 per cent. Professor Gamgee condems ovination entirely. Undoubtedly inoculation serves to increase the centres from which the contagium may extend in every direction, whereas segregation or slaughter at once diminishes the cause of the propagation of the disease, as well as the centres from whence it might spread.

Variola ovina, being a disease that runs a definite course, is not beneficially influenced by the action of medicines; on the contrary, the forcible introduction of drugs, or even of gruels, and other so-called nourishments, into the animal's stomach when it is incapable of digesting them, is calculated to do much harm. If the diarrhoea be excessive, chalk is to be mixed with the water which the sheep may drink; or if there be much fever, but no diarrhoea, chlorate, or nitrate of potash may be ordered in the same vehicle. It is essential, however, that the sheep be kept clean, have their nostrils sponged or syringed to prevent suffocation, have clean beds to lie upon, be well sheltered and kept warm, have plenty of fresh air, and, if they eat at all, be supplied with easily digested food.

On the Continent variola occurs among goats, pigs, dogs, and fowls.

Mr. Gamgee describes a form of chicken-pox in cattle, occurring on the Continent under the term varicella bovis.—(See Gamgee's Our Domestic Animals in Health and Disease, p. 256.)

**Variola Equinae, or Horse-pox.**

(Also called grease, constitutional grease, Soy's disease, and sore heels), is described by Mr. Fleming in his Sanitary Science
and Police as an eruptive vesico-pustular malady, generally diffused in the different parts of the world inhabited by the horse. With the exception of the case mentioned at page 193, I have never witnessed anything approaching to variola in the horse.

It appears, however, that the eruption, preceded by a very slight, almost imperceptible, degree of fever, may appear on the skin at different parts, or over the whole body, on the nasal and buccal mucous membranes, and occasionally on the conjunctiva.

The nasal eruption not only involves the Schneiderian membrane, but the nostrils and lips, and is apt to become confluent on the lips and the inferior parts of the limbs.

The contagium of the variola is transmissible from horse to horse, to the cow and to mankind, by contact and inoculation, but not by infection.

Variola equinae appears to be a very mild and benignant disease; and as Mr. Fleming's work contains a full description, the reader is referred to it, as well as for descriptions of the goat-pox (variola caprinae), porcine pox (variola suillae), variola caninae, and the variola of fowls. Professor M'Eachran, of the Montreal Veterinary College, reports in the Veterinary Journal, August 1877, an outbreak of equine variola in Montreal in February and March of that year.
CHAPTER XXI.

CONTAGIOUS DISEASES—continued.

RABIES.

Definition.—A disease originating in the canine, and, less frequently, in the feline race. During the progress of the malady a specific virus is developed in the saliva of the affected animal, which, being implanted through a wound, bruise, or thin epidermis without wound or abrasion, conveys the disease to other animals and to man. After an indefinite period of latency, it causes pain and stiffness in the bitten part, excitement, feverishness, inability to swallow liquids, a tendency to bite, great prostration, and death. The poison is only recognised by its morbid effects in the animal economy.

HISTORY.

Rabies (Rabio, to rave), or, as it is sometimes erroneously called, so far as the lower animals are concerned, hydrophobia, is a disease which has been known from very early times.

Mr. George Fleming, in his work on Rabies and Hydrophobia, says—"Its great antiquity is undoubted. Plutarch asserts that, according to Athenodorus, it was first observed in mankind in the days of the Asclepiadæ, the descendants of the god of medicine, Æsculapius, by his sons Podalirius and Machaon, who spread through Greece and Asia Minor, as an order of priests, prophets, and physicians, preserving the results of the medical experience acquired in the temples as a hereditary sect. They were the earliest physicians known to us, and it is not unlikely that they may have been the first to observe the madness of dogs transmitted to man." Dr. Bardsley, in his Memoir on
Hydrophobia (Cyclopedia of Practical Medicine, vol. ii.) says—
"We have already said that the disease was well known to
Homer, and applied by him, with his usual critical exactness
of similitude, to the indiscriminate havoc with which Hector
sweeps through the battlefield of his enemies."
Hippocrates alludes to hydrophobia in the faintest manner;
but Democritus, who was contemporary with Hippocrates,
according to Celsius Aurelianus, wrote upon the nature and treat-
ment of the disease. Aristotle, in his De Historia Animalium,
says that the disease is communicable to all animals but man.
Many other ancient and modern writers have described the
fearful malady: amongst the latter may be mentioned Van
Swieten, Sauvages, Cullen, Mead, Bardsey, Youatt, &c.
In 1271 wolves became affected with rabies in Franconia,
and, contrary to their usual habits, they spared the herds and
flocks and attacked human beings: upwards of thirty men fell
victims to these attacks. In 1590 canine madness prevailed in
Spain—(BLAINE.) In 1590 epizootic rabies prevailed amongst
the wolves in the province of Montpellier. The further history
of rabies may be obtained from Mr. Fleming's excellent treatise,
to which the reader is referred.
Like other epizootic and contagious diseases, its prevalence is
liable to many fluctuations, at times prevailing to a great extent,
whilst for long periods the disease is almost unheard of. During
the earlier portion of the present century rabies was very pre-
valent both in this country and on the continent of Europe,
not only in dogs, but in foxes as well. Since then there has
been an abatement in the frequency of the disease; but even
up to the present, outbreaks are not very rare. In 1869 I
witnessed the disease in a pack of hounds in the north; the
nature of the disease was detected after one man had been
bitten, and he fortunately resisted the action of the poison,
although he took no precaution against its effects. The disease
has again been prevalent in 1876-7-8 in the southern and lowland
counties of England.

CAUSES.
Opinions are divided as to the spontaneity of the origin of
rabies. Some maintain that even in the dog and allied
quadrupeds the malady never originates except by inoculation;
whilst others hold that it originates spontaneously in the dog, even in this country. Mr. George Fleming is very positive that rabies is capable of spontaneous origin, for, after discussing the opinions of Blaine, Youatt, and Maynell, who affirm it owes its origin to a wound from a rabid creature, says—"There are few now-a-days who are not convinced that it will occasionally appear in a spontaneous manner, and without any certain assignable cause. No doubt the transmission of the disease by inoculation furnishes by far the largest number of cases, and many of these, from the obscure manner in which the inoculation has been effected, appear to be due to other causes than that of a traumatic character: but, notwithstanding, the disease must have a commencement."—(Fleming on Rabies and Hydrophobia.) In this view of the origin of the malady, facts and circumstances compel me to agree with Mr. Fleming; at the same time I am fully aware that the opinions of many observers are opposed to it. Professor Dick was of opinion that rabies always originated spontaneously—from atmospheric causes—a species of catarrh, which, by extension from the nasal mucous membrane, through the cribiform plates of the ethmoid bone, involved the meninges of the brain, and produced the phrenzy, delirium, and the other train of nervous symptoms which characterise the disease. He also held the opinion that it was never caused by inoculation from the bite of a mad dog; in fact that it was a non-contagious disease.—(Veterinary Papers by Professor Dick.) This opinion of Professor Dick is still believed by a few, but fortunately very few, and the sooner it is dispelled the better, for nothing is more calculated to do mischief than the promulgation of what has been proved to be so erroneous. Rabies, once generated in the dog or cat, is transmissible by inoculation to every warm-blooded creature.

Although I hold that it is possible for rabies to appear independently of contagion, I must admit that its propagation is mostly due to this cause; but its sources of spontaneous origin, how produced, and when obtained by the victim, are circumstances which, as yet, are hidden in obscurity. The influence of climate, season, food, hunger, thirst, and domestication do not produce the disease. The evidence in support of the opinion respecting non-gratification of the sexual appetite is very vague and unsatisfactory; it, however, points to the conclusion that sexual desire ungratified, as well as severe pain, may
prove to be exciting causes of the disease, but does not prove that it ever arises from these in the absence of predisposing influences, or rabies would be much more commonly met with.

The idea that hot weather is productive of rabies is also now dispelled. The following report, arranged by Professor St. Cyr, of the Lyons Veterinary School, is very instructive, showing that rabies is even more prevalent in the temperate months than in those of extreme heat and cold:

Sometimes the annual statistics show a predominance of cases in the summer months. But according to M. Bouley's observations there is no great difference in the seasons with regard to the disease. An analysis by M. Bouley, of reports for the six years 1863-1868 gives—for the spring months, March, April, and May, eighty-nine cases; for the summer months, June, July, and August, seventy-four cases; for autumn, September, October, and November, sixty-four cases; and for the winter months, December, January, and February, seventy-five cases.

It was at one time maintained that rabies never became developed in the bitch except from contagion, and it is now advocated that it is far less frequent in females than males. Professor Coleman stated in evidence in 1830 that on the occasion of rabies entering kennels, the mad dogs bit dogs but spared the bitches. This opinion of Coleman is still believed in, more particularly by medical writers. But there can be no doubt
that bitches are as susceptible to the contagion by inoculation as dogs. This is well exemplified in what occurred a few years ago to a bitch pack of foxhounds belonging to Mr. Standish, South Shoreham, Southampton. The pack was nearly exterminated by rabies, through the disease having been introduced to the kennels by a hound which had strayed away for several days, and on its return was discovered to have been bitten."—(Veterinarian, vol. xliv.)

I think the reason for the supposition that fewer cases of rabies are seen in bitches than in dogs, is to be found in what seems to have escaped medical observers, namely, that there are fewer of them in the world. Indeed, the same explanation can be given on this point as on what appeared so strange to some during the prevalence of the cattle plague, that fewer bulls than cows were attacked by that malady.

PATHOLOGY AND SYMPTOMS.

Three circumstances in the pathology of rabies are worthy of notice, namely—First, That the period of latency after inoculation is very indefinite, and that it varies in different animals; Second, That inoculation does not always produce the disease, one-fourth of the inoculated animals generally escaping; and Third, That the disease is not transmissible to man, mammals, or birds, by the usual media at a later period than twenty-four hours after the death of the rabid animal, or after the cadaveric rigidity (rigor mortis) has completely invaded the body. The virus of rabies is contained in its most concentrated form in the saliva of the rabid animal; but it by no means follows that other parts of the diseased animal are free from its presence; indeed, direct experiments have determined that the virus is present in the blood, flesh, and other parts of the rabid animal. The virus of the rabid skunk, wolf, and hyena appears to be more virulent and prompt than that of the dog.

It was at one time believed that the virus of rabies was innocuous when the bite was inflicted by any of the herbivora. Observation on accidental cases had led to this belief, and direct experiments seemed to confirm its correctness. Girard, Vatel, Hizard, Dupuy, Lafosse, and others failed to transmit the disease from the herbivora to the dog. Professor Coleman, Sir Astley
Cooper, and others in this country believed that the disease was not communicated except by animals which "naturally employed their teeth as weapons of offence." Mr. Fleming mentions several instances where rabies was communicated by inoculation with virus obtained from cows, sheep, and even domestic fowls, and argues "that the facility with which the disease can be transmitted by different species depends, besides the activity or degree of virulence of the infecting principle, upon the organisation, habits, or rather nature of the diseased. Flesh-eating or carnivorous animals, as is well known, generally attack other creatures with their teeth, which are well adapted for wounding and tearing; consequently they are the most successful in inoculating with the poison."

The virus having been introduced into the system, generally lies dormant for a very indefinite period of time, the shortest period in the dog being about seven days, and the longest 155 days, but in rare exceptions even longer than this; in man from three days to nine months, and even ten years in rare instances; in the horse, from fifteen days to three months, and even fifteen months; in the sheep, from fourteen days up to three months; and in the pig, from a few days—eight or nine—to as many weeks, or even months. The wound inflicted by the rabid animal generally heals rapidly. In 1862 M. Renault published the results of some experiments which had been conducted with the view of determining the period of incubation in the dog. Out of 131 dogs bitten by mad dogs, or inoculated with their saliva, 63 remained well at the end of four months; the disease being developed in the other 68 after intervals varying from five to 120 days. Thus—

In 25 dogs the disease set in between the 5th and 30th day.
In 31 "  "  30th and 60th day.
In 7  "  "  60th and 90th day.
In 5  "  "  90th and 120th day.

*Symptoms in the Dog.*—There are no premonitory signs in the lower animals, at least none that can be detected—such as pain in the seat of the bite, melancholy and irritability, febrile disturbance, and stiffness about the neck and head. The dog, when the period of latency is passed, becomes restless, dull, watchful, withdraws from its companions, choosing solitude, shunning the light; hiding in corners, or below chairs or other.
furniture; being fidgety, lying down, then jumping up again in an excited, unnatural manner; it has a tendency to rove about, and if possible to escape from its room or kennel, and wander about the country. At first, the dog’s power of recognising people about it does not seem lost; indeed there are moments when the usual faculties of the dog, its affection and liveliness, seem greater than usual. Along with these symptoms there is a desire to lick anything cold, to rest the nose on a cold object, and to pick up stones, bits of wood, straw, &c. At this stage the tendency to bite is not observed, but as the disease advances the movements of the animal become unsteady; the eyes follow objects in a peculiar staring manner; sometimes the dog will stare at some imaginary object, then rush forward, and bite at anything that may chance to be in his way, or even at the air, as if he were catching flies; cushions, straw, and other objects by which dogs are ordinarily surrounded, are tossed about; the animal scratches the ground, snuffles as if on the scent; the appetite is lost, but the thirst is considerable, and the act of drinking is performed without much difficulty during the early stages of the disease. At a later stage, however, swallowing—deglutition—is performed with difficulty, or is not performed at all, owing to the spasmodic constriction of the throat; but even then the animal has no dread of water, does not shrink at the sight of fluids, but, on the contrary, will plunge its muzzle deeply into it, and endeavour to drink with great avidity. The coat is staring, the skin tight on the ribs, and the belly tucked up. The dog occasionally vomits, the ejected matter being tinged with blood; there is a brownish coating on the tongue; the nose and mouth are foul and offensive, and there is generally a flow of saliva from the mouth. A symptom is mentioned in connection with the disease in the human being, which is of doubtful presence in the lower animals, namely, the formation during the early period of the disease of lyses or eruption on each side of the tongue. If any eruption does occur, its presence is seldom detected.

The mad dog, or indeed a rabid animal of any kind, brought into the presence of one of the canine species, exhibits great excitement, exasperation, and fury, with a desire to attack and destroy what seems the object of its hatred. "The horse assaults it with its teeth and hoofs; the bull, cow, and ram with their horns; even the timid sheep, when rabid, becomes the assailant."
-(Bouley.) The females of the canine species do not always lose their maternal affection; on the contrary, the young are attended to with great affection. In the course of a day or two after the first manifestation of the above symptoms, the characteristic signs become more marked; the desire to bite is greatly exaggerated; the pupils are dilated; the conjunctiva red and injected; the eyes alternately widely opened with fury, and then closed in a dull but fierce manner. The forehead becomes wrinkled, and the looks of the animal are terrifying and repulsive; the presence of a living object excites the rage of the sufferer, causing it to spring at and endeavour to bite it. Any shining object will bring on a paroxysm of rage and excitement, and water, if the light shines upon it, will do the same; but if placed in a dark place, or where light does not shine, the dog will endeavour to drink with avidity. Intermitting with the excitement are periods of great prostration, the exhausted animal lying down in the quietest spot it can find, insensible to all surrounding objects. All at once, however, it springs up, and becomes greatly agitated; the excitement, rage, and agitation being always much greater when the animal is surrounded by noises and objects; when away from these things, in a quiet place, the fits of rage are not so great, indeed sometimes scarcely observed.

The bark of the rabid dog is unnatural; it is husky, spasmodic, and more of the nature of a howl. In some cases, the nervous symptoms are those characterising paralysis of the jaws, with inability to close the mouth; the lower jaw is dropped, the cavity of the mouth and its contents exposed, the tongue dry, and the buccal membrane of a brownish hue. This is the "dumb madness," thus called because the animal is unable to bark or howl. Rabid dogs have a strange tendency to eat filth; they have been known to eat portions of dead dogs, and to swallow hair, coals, earth, excreta of all kinds, and these remaining in the stomach present a characteristic post mortem appearance. A mad dog, when loose, will travel an immense distance in a short time, generally rushing at everything that comes in its way, but preferring to attack other creatures than man, and finally endeavouring to return home, as if prompted by some instinct. The pulse is said not to be accelerated, nor are the respiratory movements much increased, except during the paroxysms; the bowels are constipated, and the urine is high-coloured; the
gait is unsteady, the tail droops, the head is depressed, the nose protruded; the fits of rage become shorter, those of depression longer; scent, sight, and hearing are much impaired; insensibility to pain, which is generally present from the earliest stages, is more and more manifest; and finally paralysis, particularly of the hind limbs, supervenes, and if not destroyed, the dog dies, an emaciated, repulsive object, the desire to bite remaining to the last. In the dumb form, the ability to bite is lost, as well as the power to lap fluids. The exposed and protruded tongue is covered with a stringy, tenacious saliva; the desire to drink is even more intense than in the furious form, and attempts to lap and swallow become painful to witness. Squinting of one or both eyes has been observed; there is also abdominal pains in some instances, and an inflamed condition of the nasal cavities, larynx, and bronchial tubes. There is no tendency to harm and bite surrounding objects, and the dog dies from coma, exhaustion, and suffocation. Both forms of the disease terminate in death in from four to eight days. It is, however, reported that some chronic cases of rabies exist for an indefinite period.

With regard to the dread of water—hydrophobia—which has been looked upon by some as the diagnostic symptom of the disease, I may repeat that it is absent in the dog. The desire for water is always excessive; there is inability to swallow fluids, hence a dog will plunge his nose deeply into water, lap it with avidity, but owing to the thirst being still unallayed, he will become greatly agitated, and is thus often thrown into a state of fury or of involuntary spasms.

Causes and symptoms in the Horse.—Rabies in the horse occurs from the bite or contact of the saliva of a dog or cat, generally from that of the dog. The disease is manifested in a variety of ways. In some cases it commences by great apparent distress, with sudden perspirations over the body; unruliness, the horse stamping and pawing violently, finally becoming frantic, and destroying everything within its reach. In other cases, along with restlessness, there is manifested a desire to bite the seat of injury. In one case that came under my notice, where the horse had been bitten on the breast, three months before any symptoms of rabies were visible, the animal during the paroxysms continually bit the cicatrix, until at last the whole sternal region was denuded of its skin; there was also intolerance to light, great nervousness, the animal being easily startled, with fixity of the
eyes, staring at some imaginary object, the pupil being the while dilated, and the ears moved backwards and forwards, as in a blind horse, when it hears some strange sounds. At one time, during the day and night upon which it was ill, it seemed to present some signs similar to those of laminitis, shifting its weight from one foot to another, and swinging its body backwards. At the same time we noticed convulsive twitchings of the superficial muscles, difficulty in swallowing, spasm of the throat, a hoarse cough, acceleration of the breathing, a quickened pulse, and a flow of saliva from the mouth. After a while it became very furious, fought violently, destroying everything within its reach. Gradually signs of paralysis of the posterior extremities became apparent, and at last it was unable to rise. It would, however, make violent efforts to do so, and during a rapid spring or jump one thigh was fractured. The efforts to rise were not discontinued even after this accident, and so violent did it become, and so strenuous were its efforts to get at something, that the other thigh was broken. It still continued to sit upon its haunches, and to fight with its fore feet, all the while tearing at its breast with its teeth. Seeing that both tibias were fractured, the owner consented to what had long before been urged upon him—to have the horse shot.

In the stallion and mare it is stated that the sexual desire is augmented; that the stallion has frequent erections, and neighs in a harsh tone, and the mare stands with her hind legs apart, showing signs of oestrus.

The remissions and paroxysms are less apparent in the horse than in the dog. In the latter, the animal seems for a time to be almost free from the disease, but in the horse the absence of anxiety, restlessness, and exhaustion is of much shorter duration, and the fits of violence more violent and prolonged, so much so, that it soon becomes prostrated, and dies in frightful convulsions upon the second, third, or fourth day.

Hydrophobia in man is generally characterised by a sensation of intense pain in the seat of the wound, the cicatrix becoming red and irritable, the pain shooting from the extremities (if the wound be situated upon them) to the trunk. It seems most probable that this sense of pain is felt in some instances by the horse, and is manifested by the persistent efforts to bite the seat of the wound, particularly, as in the case described, if it be within reach of the teeth.
The symptoms of rabies in the cow, sheep, goat, &c., are very similar to those in the horse; in all, there is "loss or depravity of the appetite, prostration, great restlessness, increased excitability, muscular tremblings, a flow of saliva from the mouth, excitement of the sexual desire, especially in the bull, difficulty in swallowing, and manifestations of hallucinations as well as disagreeable sensations in the seat of the wound."—(FLEMING.) And succeeding to these signs are those of great violence, paralysis of the hind extremities, emaciation, and finally coma and death.

Medicinal treatment, after rabies has established itself, is of no avail.

PREVENTIVE TREATMENT.

Complete excision of the bitten surface, as soon as possible after the infliction of the injury, is the best that can be adopted. If the wound be superficial, the free application of the caustic potash (Potassa fusa) or of the nitrate of silver is sufficient; but if deep or much lacerated, the parts are to be carefully excised before the caustic is applied. Where this has been done in man seven out of ten escape, whilst if no such means are used eight out of ten die.—(BOLLINGER.) It is very difficult in the lower animals, covered as they are with hair, to know whether the part bitten be confined to any particular region of the body, no matter how carefully the skin may be searched. It is therefore advisable to have the bitten animal shaved as quickly as possible, in order that all scratches be brought into view, and that they may be dressed with the caustic. In dogs preventive treatment should not be resorted to, but the bitten animal ought at once to be destroyed. It is very true that all dogs inoculated with the rabies poison do not become mad; the risk of their becoming so is, however, so great, and the mischief they might inflict is so grave and important in its nature, that the chance of their doing such mischief should never be allowed.

The reprehensible practice of muzzling dogs in hot weather is fortunately dying away. Heat of weather does not cause rabies; the muzzling of dogs might do so, and even if it did not cause the disease in question, it inflicts much misery upon the poor animals.
LATEST EXPERIMENTS ON RABIES AND HYDROPHOBIA.

For the last four years M. Pasteur has been engaged in conducting experiments with the view of obtaining an attenuated virus, and with which he has succeeded, by inoculation, in rendering animals absolutely proof against the poison of rabies. Although the microbe of rabies has not been satisfactorily demonstrated, most pathologists are satisfied of its existence, and that its virulence may be modified or intensified in animals unfavourable or favourable to its growth. Thus the virus inoculated from an ass to a rabbit will not kill the latter, but if passed on to another rabbit, and then to a dog or man, it will be fatal.

M. Pasteur's experiments are as follows:—"If the virus of rabies be transmitted from the dog to the monkey, and then from monkey to monkey, it will be found that after each transmission the virulence of the virus has become enfeebled. If the virus, thus enfeebled, be transmitted to a dog, or an animal of that species, it will remain still attenuated. By a few transmissions of the virus from monkey to monkey, there can easily be obtained a virus so attenuated as shall never communicate, by hypodermic inoculations, the disease to a dog. Inoculations by trephining of such virus will likewise produce no result; but an animal will, notwithstanding, be rendered thereby proof against the disease. The virulence of the virus becomes, on the contrary, augmented in its passage from rabbit to rabbit. If a dog be inoculated with virus thus augmented in power, a far more intense form of the disease will be manifested than that apparent in ordinary canine madness, and it will invariably prove fatal."

By applying these and other observations, M. Pasteur obtained virus of different degrees of virulence, and succeeded, by inoculations of the milder qualities, in preserving animals from the effects of more active and mortal kinds. For example, after several days longer than the shortest incubation term, M. Pasteur extracted virus from the head of a rabbit which had died of the disease, after having been inoculated with attenuated virus, and inoculated successively two other rabbits. Each time a dog was inoculated with the virus, which, as has been seen, would increase each time in virulence. The result was
that the dog was ultimately rendered capable of bearing a virus of mortal strength, and became absolutely proof against canine virus. M. Pasteur anticipates that the time is still distant when canine madness will be extinguished by vaccination, but, pending that consummation, he feels pretty certain that he will be able to avert the consequences of a bite from a mad dog. He says—"Thanks to the duration of incubation after a bite, I have every reason to believe that patients can be rendered insusceptible before the mortal malady has had time to declare itself."

M. Pasteur's anticipations were put to the test by a Commission appointed by the Minister of Public Instruction, consisting of M.M. Bouley, President; Paul Bert, Bécland, Vulpian, Tissot, and Professor Vilemin.

Forty dogs were submitted to the bites of rabid dogs. Twenty of these healthy dogs had been previously inoculated with attenuated virus, whilst the other twenty were not inoculated; the rabies showed itself exclusively among the uninoculated dogs.

M. Pasteur was requested by the Commission to perform his proof experiments in a more expeditious and certain manner than by only submitting healthy dogs to the bites of rabid ones. He having found, first, that if nervous matter from the bulb of the brain of a rabid animal be inserted on the brain—by trephining—of a healthy dog; second, that when the virus was injected into the vein; and third, that when dogs were repeatedly bitten about the head by rabid ones, a rapid and fatal rabies occurred within twenty days—therefore proceeded to carry out a series of experiments on protected and non-protected dogs, with the result that none of the protected animals had, up to 10th July 1884, shown any signs of the disease, whilst twelve of the unprotected ones, including two which were repeatedly bitten about the head, had succumbed to the disease.

The dogs still remaining healthy are to be watched by veterinary surgeons for a year, to see whether the inoculations hold good permanently or only temporarily. If rabies be not of spontaneous origin, and if the experiments all turn out successful, there seems to be no reason why rabies should not be entirely extirpated.

PATHOLOGICAL ANATOMY.

From the symptoms observed during life, the conclusions natu-
rally suggests itself that the brain and its membranes are the seat of organic lesions. Indeed, the specific action of the poison appears to be exercised, particularly in the first instance, upon the medulla oblongata and the par vagum, the branches of which seem to lose their natural properties; hence the difficulty in swallowing, the depraved appetite, alteration of the voice—or its entire loss in the dumb form—as well as the convulsions of the respiratory muscles, are all due to derangement of this nerve; and as the nervous system of the animal becomes more and more deranged, complete paralysis of the respiratory muscles occurs, and the animal dies from asphyxia.

The principal post mortem appearances are oedema or congestion, sometimes in patches, of the brain and spinal cord, particularly at the base and plexus choroides, effusion into the arechnoid space, cerebral ventricles, and the cerebro-spinal substance, and softening of the membranes. On the lower surface of the medulla oblongata, at the origin of the seventh, eighth, and ninth pair of nerves, the membranes are generally highly injected, thickened, softened, and matted together. The liver, kidneys, spleen, and the muscular system are congested. The bladder is empty, and its mucous membrane covered with petechiae. The lungs are greatly engorged with blood. The blood in the vessels is but imperfectly coagulated, often black and tarry, sometimes bright and red, in appearance. The mucous membranes of the pharynx, esophagus, stomach, and bowels are either greatly congested, with extravasation of blood on their surface, or diffusely inflamed. Patches of extravasation are particularly met with on the gastric mucous membrane, and account for the hemorrhagic vomiting which is sometimes witnessed during the illness. The contents of the stomach are generally of a peculiar nature, consisting of hay, straw, stones—in fact, of a collection of the most incongruous materials, which, owing to depraved appetite, the animal has picked up during life. This appearance is of great value, as it proves most conclusively that the dog has died ravid.

The tongue is often wounded by the teeth; its papillae congested; and the salivary glands enlarged and vascular. In “dumb madness” the congestions, more particularly those of the upper part of the respiratory and digestive tracks, are developed to a greater extent than in the other form of the disease.
CHAPTER XXII.

CONTAGIOUS DISEASES—continued.

GLANDERS AND FARCY (EQUINA).

Definition.—A malignant, contagious, and fatal disease, due to the introduction into the animal economy, or of generation within it, of a virus (said by Dr. Strück of Berlin to consist of bacilli about the same size as those of tuberculosis) which, infecting the whole system, shows specific effects more especially upon the Schneiderian mucous membrane, the lungs, and upon the lymphaticerian glands and ducts. Glanders, and its variety farcy, originate spontaneously in the horse, ass, and mule, and are capable of transmission to man, in whom the virus seems to increase in malignancy; sheep, goats, dogs, the feline species, and even to mice and rabbits. Cattle, pigs, and fowls resist the action of the contagium, even when inoculated.

HISTORY.

Glanders was described by Aristotle, ¹ by Vegetius, ² and other early writers, under the terms morbus humidus, cymoira, capitis morbus, &c.; and its variety farcy, as morbus farciunosus, vermis equi, vermis volaticus, farcina equi, &c.

Glanders is a disease of temperate climates, rare in hot and very cold countries. The contagious nature of glanders was for a long time a disputed point; it is, however, now determined beyond question, the only difference of opinion being its capability of originating spontaneously or not; some veterinarians maintaining that it originates by contagion only, whilst others—and with whom I agree—contend that it is capable of

¹ Aristotle, De Hist. Anim., lib. viii. c. xxv.
² Vegetii Remati Arcti Veterin., lib. i. c. VII.
spontaneous origin, and of propagation by contagion and infection.

Glanders may occur under at least four forms, namely, acute glanders, chronic glanders, acute farcy, called by some bud farcy, and chronic or button farcy.

CAUSES.

The remote causes of glanders, though not yet clearly understood, are often found to arise from many debilitating influences, such as old age, bad food, over-work, exhausting diseases, and general bad management; from specific miasmatic or animal poisons, such as those generated in localities where large numbers of horses are congregated together, in camps, barracks, large cab or other establishments, even where the stables are well ventilated, lighted, drained, and the animals well attended to in every way, but more particularly where the stables are ill ventilated, badly drained, dark, and foul. Horses, when crowded on board ship, are very liable to this affection, and the Arabs in transporting their horses from Arabia to India always choose that part of the year when the passage is shortest, lest the accidents incident to a long voyage might oblige the hatches to be closed, and want of ventilation promote the development of glanders. I have also observed that glanders is developed in new stables, where the walls are not thoroughly dry, where in fact, in common language, they are said “to sweat”; and, finally, glanders occurs as a sequence to exhausting diseases, more especially if the animal be old, or of a bad constitution. These causes, and a generally vitiated condition of the animal system, may be said to produce glanders—(1.) By causing the introduction into the blood of vitiated or decomposing material generated in the external surroundings of the animal: (2.) By inducing the formation of degenerated material within the animal system: (3.) By preventing the excretion of the degraded constituents normally generated within it by natural tissue changes, or excessively formed within it by various disordered functions, or introduced into it from without.

The most common forerunner of glanders, more particularly of that form of it known as farcy, is the disease commonly called diabetes insipidus or polyuria. It cannot be said that in diabetes
there is any obstruction to the excretion of degraded tissue; indeed, the reverse is the case, excretion of urine being enormously increased. If we look deeper into the matter we shall, however, see that the polyuria is but a result of rapid tissue changes, rapid emaciation of the body being a most prominent symptom, with debility arising from degradation of tissue, and from the presence of the degraded materials within the circulatory fluid. So apparent is this condition, that it has been truly said that diabetes, when arising from no cognizable cause, is often indicative of a general breaking-up of the constitution.

Although glanders and farcy are one and the same disease, differently manifested, farcy is more frequently developed spontaneously than glanders. This circumstance, and the possibility of recovery from mild attacks of farcy, has led some to conclude that they are two separate diseases; but direct experiment has proved that the virus is identical in both forms of the disease. The discharge from the nose of a glandered horse, when introduced into the systems of other horses, may in one produce glanders and in another farcy, whilst the pus from a farcy ulcer may produce in the inoculated animal glanders, farcy, or both; and the common termination of farcy, if a horse affected by it be allowed to live a sufficient length of time, is glanders, and of glanders, farcy. Such an animal is described as being “both glandered and farcied.”

CONTAGION.

Glanders, and its variety farcy, spontaneously developed, are highly contagious and infectious, and when once introduced into a stable are almost certain to spread amongst the horses there located.

The specific poison has been introduced into the system both by the skin and mucous membranes. By inserting the virus under the skin with the point of a lancet, by rubbing the greasy heel of a horse, and by inoculating the mucous membrane of the nose, the disease has been produced.

With regard to the transmission of the contagium of glanders otherwise than by actual contact, opinion seems to be divided, some writers maintaining (and the experiments brought to bear upon their conclusions are formidable) that it is impossible to com-
municate it in any one of its forms by compelling healthy animals to inhale the expired air of those suffering from the disease, whilst others maintain that it is both contagious and infectious. The first opinion, if acted upon in every day practice, would, I opine, lead to disastrous results, and should not be entertained; for even if we were to grant that the virus is contained in the discharges from the ulcers, numerous experiments have proved that pus and other organised cells float in the atmosphere; the specific virus contained in these cells may thus be easily conveyed from one animal to another. Again, it must not be forgotten that in some instances glanders may exist without any external manifestations, i.e., without discharge from the nose, nor from farcy ulcers, but even in this form it is capable of propagation.

Farcied matter, made into balls, and introduced into the stomach of a horse, has caused glanders; and whichever way the virus has been introduced, once absorbed, it infects the whole blood, as has been proved by the experiment of the late Professor Coleman, who says—"I have produced the disease by first removing the healthy blood from an ass until the animal was nearly exhausted, and then transferring from a glandered horse blood from the carotid artery into the jugular vein of the ass. The disease in the ass was rapid and violent in degree; and from this animal, by inoculation, I produced both glanders and farcy." Professor Coleman also experimented on asses with virus obtained from man. He directed two asses to be inoculated with matter taken from the arm of a man labouring under the malady, which resulted from a puncture received in dissecting a glandered horse, and both asses died of glanders. These experiments have been repeated, and similar results obtained by Girard, Hering, and Leblanc.

**Period of incubation.**—Like all morbid poisons, that of glanders has its period of latency, which is, however, generally short. In the ass, the submaxillary glands become swollen and tender the second or third day after inoculation, and a discharge from the nostril occurs from the third to the sixth day. In some instances the incubation is much longer—from one to three or even six weeks; one case is mentioned in the *Procès-verbal de l'Ecole de Lyons* where the disease did not appear till the end of the third month after inoculation. The matter in this instance
was obtained from a farcy ulcer, and the disease appeared at the precise point of the inoculating puncture.

ACUTE GLANDERS.

*Symptoms.*—The disease, preceded by increased temperature of the body, appears suddenly, ushered in by rigors, sometimes of a most persistent character. In one case which fell under my notice the rigors continued without intermission for three days and nights, at the end of which time a sanguineous discharge issued from both nostrils, the Schneiderian mucous membrane became violently inflamed and deeply ulcerated. More commonly, however, the rigors are not so persistent, but they are always more or less observable; the temperature is sometimes as high as 106° or even 109° F., the breathing is accelerated, the pulse feeble, rapid, and even dicrotomous, the heart’s action palpitating and accompanied by metallic tinkling, the appetite fails, the pituitary membrane, at first of a dark copper colour, with patches of ecchymosis of a dark red hue, becomes purple, and the patches are rapidly converted into pit-like, ragged-edged ulcers, from which issues a copious sanguineous discharge. The submaxillary lymphatic glands enlarge. Other lymphatic glands inflame, enlarge, suppurate, burst, and expose raw, unhealthy-looking sores, from which issues a more or less ichorous and irritating purulent material. The eyes are weak, and a discharge issues from them; the nostrils are often swollen. The breathing is hurried, irregular, and impeded by the swelling of the nostrils, and by the glutinous discharge drying around them; abscesses speedily form along the course of the lymphatics of the face. The urine is pale, watery, and increased in quantity.

Acute glanders is rapidly fatal, and the *post mortem* examination reveals the following lesions:—The mucous membrane lining the nasal passages and facial sinuses is violently inflamed, and covered with a numerous crop of pustules and ulcers, from which a purulent or sanguineous fluid is freely discharged. In many instances, and where the disease has been very rapid, the inflammation is diffused over the whole surface of the mucous membrane, which then presents one uniform purple or purplish-black hue, its structure being exceedingly soft and friable from degene-
GLANDERS AND FRACT.

raction, and it is easily detached from the bones. Now and
then it will be found that the nasal bones, the septum nasi, the
turbinate and ethmoidal bones, are in a state of necrosis, their
surfaces bathed with a purulent discharge, and wholly separated
from the mucous membrane. The intermaxillary glands are
congested and surrounded by a yellowish exudate, and the lymph-
atic ducts leading from them are thickened and congested.

The lungs in almost every case of glanders, acute and chronic,
are more or less inflamed. Now and then the inflammation is
diffuse, embracing perhaps the whole of one or a part of both
lungs, whilst in others it is limited to some of the lobes, and
presenting the appearance of a series of tumours and patches
of congestion of different sizes, and in varying stages of
development, scattered throughout the lung tissue. Many of
these inflamed spots will be found to contain pus; hence they
have been termed tubercles, and the nature of the disease has,
from this supposition, been laid down as tubercular; and so
close is the relationship between tubercle and glanders, that the
editor of the British and Foreign Medico-Chirurgical Review says
—"It is in glanders that Villemain thinks he has found the
closest marks of analogy with tubercle, not only in its anatomy,
but also in its symptoms and causation. He seems to have been
conducted from the study of glanders direct to the inoculation
of tubercle. The characteristic lesion of glanders is a small tubercle,
which is strewn either in the mucous membrane of the nasal
passages, or in the lungs, or, more rarely, in the liver and spleen.
At first a greyish-white, firm granulation, composed of cells and
nuclei apparently developed by hyperplasia of connective tissue,
it soon tends to soften centrally and form ulcers on the mucous
membrane, cavities in the lungs. Like miliary tubercle, it occurs
isolated or in clusters. Together with this little granulation,
streaks and bands of fibrous tissue, as well patches of cheesy
infiltration, are not infrequently met with in the lungs of glan-
dered horses. It is interesting, too, that the same doubts have
been raised concerning the real nature of these 'infiltrations'
in glanders as in tubercle. They are regarded by Villemain as one
form of glanders, just as in man they are one form of tubercle.
As to which is the part primarily affected in glanders—the nasal
membrane or the lungs—there is some difference of opinion;
Virchow maintaining that the deposits in the lungs are always
secondary and by metastasis from the nasal membrane; Phillippe and Bouley being convinced by repeated post mortem examinations that the primary lesions are always in the visera, more particularly the lungs, and that the formations in the nasal membrane are invariably secondary. If, say they, a horse has the 'jetage' (discharge from the nose), it is already thoroughly glandered. It really matters very little which part of the body is first affected. In either case the analogy with a tubercular outbreak remains as strong as can be. The intestinal ulceration of tuberculosis—in which we see the counterpart of the nasal ulceration in glands—is more often secondary to the pulmonary disease, but occasionally shows itself before any evidence of mischief can be detected in the lungs. Again, glandular enlargement of a severe and persistent kind constitutes an important part of glanders, as it does of tubercle. The mode of invasion is likewise identical in the two diseases; now acute, foudroyant, destroying life in a few days as by an overwhelming blood poison; now chronic, so as to last for years. Further, in the chronic form, the same recurrence of acute attacks complicating and adding to the chronic mischief is observed in glanders as in tuberculosis. To read a description of chronic glanders is, Mutatis mutandis, to read an account of chronic phthisis. It is, therefore, not surprising that Dupuy goes so far as to say that glanders is a tubercular disease in the horse. In speaking of the supposed causes of tubercle, we purpose presently to follow out still further this remarkable thread of resemblance; but for the present it will suffice to say that glanders is transmissible by inoculation, and contagious from horse to horse, and that it is also unmistakeably communicable from horse to man. Can we hesitate to believe, says Villedin, that the parallel between tubercle and glanders must hear find its completion? To conclude, glanders and tubercle are so closely akin that they must be looked upon as nearly related species of the same genus."—(Braithwaite's Retrospect of Medicine, vol. lviii.)

Whilst admitting the close resemblance between glanders and tuberculosis, we must hesitate to admit their identity, for the broad fact remains that inoculation with glanders produces glanders, whilst inoculation with the caseous matter of supposed tubercle is followed by the development of nodules, which rapidly undergo a caseous change.
The form of pneumonia seen in glanders is very characteristic, the inflamed part resembling an infiltration, with thrombi in the blood-vessels—gangrenous, emphysematous—of a greenish-black colour, and rapidly decomposing after death. The line of termination or demarcation between the healthy and inflamed lung tissue is often abrupt and very distinct. The tracheal and bronchial mucous membrane is more or less highly inflamed; in some instances covered with petechial spots or deeply ulcerated, and thickly covered with an unhealthy discharge, which exhalas a gangrenous odour.

The changes which occur in the lymphatic glands in glanders are characteristic. The glands, irritated by the specific poison, become congested and enlarged; their cellular elements proliferate more or less rapidly, and are mixed with a citron-coloured exudate, which invades the surrounding connective tissue. In a few days the glands become dense and hard to the touch, more or less lumpy on their surface, and those in the submaxillary space fixed to the jaw by the now inflamed and indurated vessels which enter their deeper seated parts.

CHRONIC GLANDERS.

Symptoms.—In some instances the disease presents itself in such a mild form that the general health is scarcely affected. There will be a discharge from one or both nostrils, generally from one nostril, and that very often the near (left) one. The submaxillary lymphatic glands are swollen and hard; the hardness and swelling are of a remitting nature, very often varying in size in a short period. For example, a horse may be left at night with scarcely any discoverable swelling, and found in the morning with a hard knot under the jaw, which is both easily seen and felt. The swelling may continue for several days, afterwards slowly disappear, and then reappear as rapidly as before. This condition may exist before any discharge issues from the nose, and a horse so affected is elegantly said to be “jugged.” If the nostril of such a horse be examined, it will be found to be paler in colour than natural, or perhaps tawny, coppery, and sometimes of a dull leaden hue. The discharge of glanders presents a starchy or glue-like appearance, adheres to the nostrils, where it dries and accumulates, causing the nasal opening of the affected side to appear smaller or more contracted than in health.
These appearances, in addition to a weak or debilitated condition of the eye of the affected side, may be all the symptoms present in a case of chronic glanders; indeed in some instances there may be nothing but the discharge from the nostril to lead the practitioner to suspect anything wrong with the animal, and the diagnosis is consequently very difficult, more particularly if the case is a solitary one; but where glanders is found to exist in a stud of horses, any suspicious symptom becomes significant. I have said nothing about the glanders-ulcer, because in many instances of chronic glanders the ulcer is undiscoverable; indeed in some rare cases ulcers are never found either before or after death. For this reason Percivall limited the term chronic to that form in which no ulcers could be detected. He says, however, that they are always present in the frontal sinuses.

Before describing the more common form of glanders—namely, that in which ulceration is a characteristic sign, and called by Percivall "subacute glanders"—I shall call the reader's attention to what may be termed a spurious form of glanders; that is to say, a form of glanders where there is neither discharge from the nose, ulceration of the Schneiderian membrane, nor enlargement of the submaxillary glands; but in which all these may become apparent if the animal live long enough. This form may be appropriately termed pulmonary glanders, and the symptoms are as follows:—The animal is languid, unthrifty, loses flesh, sweats on the slightest exertion; the visible mucous membranes are pale; diarrhoea is easily induced, and there are occasional attacks of diabetes. There is a dry, dull, soft cough; the appetite is very capricious; the hair is easily removed from the mane and tail; the legs are sometimes very fine, sometimes more or less oedematous. The affected animal may remain in this unsatisfactory condition for several weeks, or even months, and may die from marasmus and debility without any other symptoms becoming apparent, or all the signs of glanders and scabby very rapidly develop themselves, and carry it off in a few days. If a case of this kind occur in the horse first attacked in a stud, or if in a horse where no others are kept, it is impossible to arrive at a satisfactory conclusion as to the nature of the malady, and the practitioner must be contented to pronounce it "chronic pneumonia," the abnormal sounds of that disease being more or less detectable by auscultation. But when it occurs in
a stud where glanders has existed, or where it exists, no difficulty need be felt in pronouncing as to the true character of the disease.

The post mortem examination of a horse which has presented these symptoms prior to death will reveal the lungs studded with nodules, varying in size from a pin’s head to a pigeon’s egg, or even larger. Some of these nodules will be found to consist of an organized exudate—lymphoma—of a pearly grey appearance, and rather hard; others will contain pus enclosed in sacs—vomicae; whilst others will be found in a degenerated condition, and presenting the appearance of rotten cheese, the degraded material consisting either of inspissated pus or a caseous metamorphosis of the exudate. Some of the deep-seated lymphatic glands will be found enlarged, or in a suppurating condition, and one remarkable pathological change, which I have seldom failed to observe either in this or any but the most acute form of glanders, the splenic veins are filled with thrombi; the larger branches in particular being generally obliterated by hardened fibrinous coagula.

Glanders, as most commonly met with in this country, presents the following signs:—The horse is generally more or less off its feed, has a tendency to shiver on the slightest cold; its coat is rough and unhealthy, “has lost the bloom of health;” it may or may not cough; the appetite is capricious; and perspiration is induced by slight exertion. There is a discharge of a starchy or gluey material from one or both nostrils; the discharge is often tinged with blood. In some instances recurrent haemorrhage from the nostril is a premonitory sign of glanders. The mucous membranes are pale and unhealthy, and that covering the nasal chamber, from which the discharge issues, is studded over with deep, pit-like ulcers. The ulcers are characteristic, being excavated, as if cut with a punch, but after a time they become ragged at their edges, irregular, enlarged in all directions, and confluent. The spaces between the ulcers are covered with hard yellowish pimples, which soon ulcerate. The eye of the affected side is weak, and looks smaller than its fellow, and an unhealthy discharge often issues from it over the face. The submaxillary lymphatics of the same side enlarge and form a tumour—sometimes single, sometimes lobulated—which is more or less firmly adherent to the surrounding tissues.
This tumour seldom suppurates; occasionally, however, I have seen it developed into an abscess, which, after having discharged a little unhealthy pus, has healed slowly, the tumour, however, continuing as large, or even larger than before the suppuration.

If the animal is allowed to live, these symptoms remit, and some of the ulcers may cicatrize, but they finally increase in intensity, and upon the application of any slight cause of disorder become rapidly developed into those of acute glanders. If the horse is well taken care of, it may do moderate work for a long time whilst affected with chronic glanders. In the course of time, however, symptoms of farcy appear; it then becomes a loathsome object, and if not destroyed, acute glanders sets in and carries it off in a very short time.¹

Chronic glanders is more frequently seen than the acute form in the horse, but in the ass and mule the latter is more frequently met with.

In acute glanders the period of incubation is very short—from three to seven days; whilst in the chronic form the period is very uncertain, extending from a few days to several months.

ACUTE FARCY.

This form of the disease occurs either as the result of direct inoculation with the discharge of glanders or farcy; from infection through the medium of the air; as a sequel to some exhausting disease, particularly diabetes; from old age and other debilitating influences.

Symptoms.—The primary signs are those of fever, elevation of the animal heat to 106° or even to 108° F., rigors, loss of appetite, and swelling of the extremities.

The swellings of acute farcy, commonly confined to the extremities, manifest themselves by engorgement of a whole limb, resembling the swellings of acute lymphangitis or oedema, but presenting an uneven surface, increasing and decreasing suddenly, and attended with pain and lameness. When the engorgement of the areolar tissue diminishes, enlarged lymphatic glands and vessels will then be detected, forming buds and cords. The

¹ For the differential symptoms of glanders and other diseases accompanied by nasal discharge, see Principles and Practice of Veterinary Surgery, page 493.
swellings, which are due to inflammation of the ducts and valves, point and burst, giving exit to a thin, purulent, yellowish material, which generally soon dries, and forms a yellow crust on the surface of the ulcer. These buds are generally found in groups, and away from the articulations.

In some instances farcy manifests itself by, first, the formation of a single painful swelling, which runs on to suppuration, on the flexor tendons of a limb, below the hock or knee, and from which enlarged lymphatic vessels may after a time be traced. Other swellings form on various parts of the affected limb, with intervening enlarged lymphatic vessels, which ultimately burst and present ragged-edged, confluent, unhealthy-looking sores that discharge copiously.

In other instances, farcy is preceded by symptoms of rheumatism in some part of the body. Sometimes the muscles of the neck become acutely painful, and very often, but not always, swollen. The pain and swelling may disappear as suddenly as they came, and appear in some other part of the body, and this may occur repeatedly before any diagnostic signs of farcy manifest themselves; or the seat of pain may be the muscles of the chest, simulating pleurodynia or pleurisy, the animal groaning if made to move sharply or suddenly, and with a catch in his breathing diagnostic of thoracic pain. Again, one limb may suddenly become swollen and painful, causing much lameness. The tumefaction, heat, and lameness may recede, and attack the other limb; and such attacks may appear repeatedly and for several months, the animal's general health during the remissions being scarcely affected; but at length the disease assumes a more marked character, and unmistakeable symptoms of farcy appear, or glanders results, unprecedented by any true signs of farcy. In other instances, extreme lameness may appear in a limb without any traceable cause, and continue for days, or even weeks, without inducing any observable local change; generally, however, farcinous engorgement succeeds, and relieves excessive pain, and as a rule extreme pain is not of long duration. But it may be safely stated that equina is manifested in such a variety of ways as sometimes to mislead the most experienced.
CHRONIC FARCY.

In chronic farcy the local symptoms generally precede any apparent febrile disturbance; but if the thermometer be employed for the examination of all horses in a stud where glanders exists, some elevation of the temperature of the body may be apparent in the infected prior to the development of any local symptoms.

These local symptoms consist of circumscribed inflammatory swellings, running in the direction of the principal vessels, which suppurate and burst, without much accompanying engorgement of the surrounding areolar tissue.

The circumscribed elevations or buds are connected together by corded lymphatic vessels, and wherever a valve is situated in a lymphatic duct, there a swelling will usually appear, and a bud will form. The buds are ranged in groups about the inner and outer aspects of the thigh, fore arm, flank, neck, and head. From the circumstance that the enlarged cords and buds run in the same direction as the veins, the old farriers concluded that farcy was a disease of the veins; dissections, however, soon expelled this delusion, and the reason why the disease accompanies the vessels is explained by the fact that the lymphatics and blood-vessels run in company.

In some instances farcy is found confined to the cervical lymphatics. An examination of the neck along the course of the jugular vein will enable the veterinarian to detect the lymphatic duct swollen, hard, and presenting irregular knots along its course. Suppuration seldom occurs, but the animal sooner or later presents signs of glanders or of farcy in some other part of the body.

Chronic farcy differs from the acute only in intensity and duration, and is the only form of equina which is at all amenable to treatment.

The Contagious Diseases (Animals) Act provides, however, for the destruction of glandered and farced horses. I think an exception might be made with regard to the milder forms of chronic farcy, provided always that the animal be isolated and properly attended to, medically and otherwise. I entirely dis-
Glanders and Farcy.

approve of the practice of working animals whilst affected with this malady, and would recommend the strictest surveillance by properly qualified inspectors.

The treatment of farcy is both local and general. The swellings may very often be dissipated by the application of blisters, the ointment of the binioidide of mercury being particularly effective, and the ulcers stimulated to healthy action by caustics, or the actual cauterity. Some practitioners prefer the actual cauterity to all other remedies. For my own part, I think the stick nitrate of silver freely applied is more successful. The parts around the suppurring sores are to be kept very clean, and both sores and surrounding skin frequently washed with antiseptic remedies, such as dilute carbolic acid, or a solution of chloride of lime.

The constitutional treatment must be directed to the support of the system by good food—oats, beans, &c.—and by tonic remedies, particularly the preparations of iron and copper; arsenious acid, combined with cantharides, chloride of potash, nux vomica, quinine, gentian, &c. A very favourite remedy, and one that answers uncommonly well, is the diniodide of copper, combined with a vegetable tonic, the diniodide being given in doses varying from two to three drachms. Another most excellent tonic is the arsenite of strychnia; and I have been in the habit of giving a modified form of it, namely, five grain doses of arsenious acid, with one drachm of nux vomica, for several days. I have no experience of the bichromate of potash, recommended by Mr. Moore of London.

The Antiseptic Preventive Treatment of Equina.

When glanders appears in a stable of horses, in addition to the removal of all affected animals, it is most essential to attend carefully to the ventilation, drainage, food and water, and to the cleansing and disinfection of the stables, fittings, harness, and other appurtenances, the removal of contaminated wood-work, the painting of all fixtures, lime-washing, or even scraping and then lime-washing—the wash to contain a pint of crude carbolic acid to every bucketful—and to the prevention of overcrowding, exhaustive work, and all debilitating influences. It has been
found serviceable to administer for several weeks to all horses in the same stud, with every meal, two ounces of the hyposulphite of soda, or two drachms of the chlorate of potash. American practitioners laud the hyposulphite in farcy, and say that the sores require no treatment except cleanliness. This method is well worthy of an extended trial in this country.

STOMATITIS PUSTULOSA CONTAGIOSA OF THE HORSE.

The Veterinary Journal for November 1878 contains a report on this disease by Professors Eggeling and Ellenberger of the Berlin Veterinary College, translated from the Archiv für Wissenschaftliche und Praktische Tierheilkunde by G. A. B. I am indebted to Mr. Fleming for the woodcuts illustrating the eruptions characteristic of the disease.

They state that during the summer of 1876 several cases of a contagious disease appeared in and outside the clinic of the Berlin Veterinary College, presenting phenomena similar to those of variola, and chiefly affecting the mucous membrane and external integument.

Some cases outside the clinic had been declared by the inspecting veterinary surgeons to be suffering, or suspected of suffering, from glanders.

Most of the patients were from four to five years old, in good condition, and showing but slight indications of general illness; having on the whole a lively appearance, and smooth and glossy coats, and eating bran mashies with good appetites; but whilst eating hay, large quantities of saliva flowed from the angles of the mouth.

Some of the horses stood with depressed and stretched-out heads; the temperature of the skin was warmer than natural, although the ears and extremities were cold. The pulse was 60 per minute, and full; the respirations normal. Even those showing the worst symptoms ate their food eagerly, but evinced pain during prehension, masticated slowly, swallowed with difficulty, and saliva was secreted in abundance, and a fine chlorophyll-green discharge flowed from the nasal cavities; when water was taken large quantities of it was returned through the nose. The Schneiderian membrane was of a red rose colour;
both the submaxillary glands were enlarged to about the size of a hen's egg—hard and knotty—but unattached to the submaxillary bone or integument. The oral mucous membrane became intensely hot, red, and covered by a tenacious secretion. On passing the hand over it, small firm nodules, varying in size from a millet to a lentil seed, could be felt. These nodules rapidly increased in number and size, extending to the cheeks, tip of tongue, frænum linguae, inferior surface of tongue and upper lip, and in one or two days later their summits presented a white appearance, or the epithelium was removed, and a small ulcerated surface was apparent, and in four or five days the ulcerations were numerous, the dental surface (see Fig. 7) of the lips, the tip of the tongue (see Fig. 8), frænum, and inferior surface of it, being specially affected.

About the sixth or eighth day the ulcerations began to heal. Four horses condemned as glandered, presented, in addition to the above phenomena, ulceration of the external integument, namely, on the upper lip, cheeks, and anterior extremities. The ulcerations of the skin in two of these cases were more numerous than in others observed before or since, and the prescapular glands were swollen in one case.

In one case the nodules appeared between the external nares and Schneiderian membrane; in another, on the skin of the breast and fore extremities; in fact, on those parts on which saliva is most likely to be thrown, several nodules about the size of a pea, and two ulcers about the size of a fourpenny piece...
were seen. On no other parts of the body could nodules or ulcers be found.

Fig. 9.—Ulceration of skin of lips and cheeks.

The disease runs a rapid course, the small nodules on the mucous membranes soon becoming prominent, presenting a smooth, round, and sharply defined surface, with a yellowish-white summit, or the epithelium becomes removed, and they are transformed into round or slightly angular ulcers, varying in size from a fourpenny piece to a shilling—they, in their turn, becoming encrusted, somewhat resembling pus scabs. Microscopically examined, they were seen to consist of pus corpuscles and epithelial cells, with red blood corpuscles. Fungi and micrococci were also present. The ulcers on the legs were generally larger than those on the mucosa.

The healing process commenced in the ulcers about the sixth or eighth days, and all the cases under treatment resulted in the animals getting quite clear of the disease in from twelve to fourteen days.

Experiments as to the transmissibility of the disease by inoculation and infection were made on sixteen horses, two cattle, four sheep, one goat, three swine, two dogs, one rabbit,
and five men, with varying results. Four men and a number of horses took the disease by natural contagion, independently of experimental inoculation.

Below are given a few extracts from the diary kept during the course of the experiments.

22d May.—A seven months' old foal was successfully inoculated on the dental surface of the lip, the left ear, and the internal surface of the left fore leg; the resulting eruption was extensive and confluent, and the disease protracted, not having completely ceased until the twenty-first day.

30th May.—A healthy foal was placed with the above one, and another was inoculated on the vaginal mucous membrane. The inoculated one gave a negative result, but in the healthy foal the result was positive, the disease running its course, and terminating in eleven days.

31st May.—Another horse was placed with the last-mentioned foal. On the 2d of June nodules were formed, the disease terminating on the 12th. Others were inoculated with similar results, and the four foals which passed through all the stages of the disease before were again inoculated, but did not become infected a second time. One showed three small nodules, which disappeared without ulcerating in a few days.

24th May.—A calf was inoculated on the vulva. No symptoms appeared, and it was again inoculated on the 30th, after which the disease fully established itself, terminating in eight days. Others were inoculated with similar results.

23d May.—Sheep were inoculated with negative results. In pigs the result was also negative. In dogs, nodules appeared, but no ulceration. Rabbits were not affected.

29th May.—Mr. Häusel (student) inoculated himself. There was redness and unpleasant itching and swelling of the part, the formation of a pustule, over which a yellow-brownish crust formed, which fell off in fourteen days, leaving a deep cicatrix.

Other four gentlemen inoculated themselves without infection.

A groom was infected, the disease running the course above described, he becoming quite convalescent in twelve days.

In contrasting this disease with that of glanders, the authors say—In a superficial examination the malady might be easily mistaken for that of glanders. In favour of this diagnosis we had its contagious character, the feebleness of the discharge
from the nostrils, the swelling of the submaxillary and pre-scapular glands, accompanied with the formation of ulcers in the external integument and Schneiderian membrane (the last in one instance only). Close examination and observation, however, brought to light important differences between this disease and glanders. The most striking deviation was the appearance of the ulcer itself, which presented quite a different character to that of glanders. In these instances the ulcers were round, with sharply defined borders, varying in size from a fourpenny piece to a shilling, the edges neither being serrated nor swollen as they are in glanders. The ulcerations were isolated, and independent of the course of the lymphatics. For instance, those on the lips and cheeks were irregularly distributed, and covered with a brownish white scab projecting somewhat above the surrounding skin. When this was removed a white granular ulcerated surface presented itself. The ulcers were generally superficial, and rarely attained any depth, hardly ever reaching the subcutis. After the sixth day they readily healed.

The disease lasted in individual cases from twelve to fourteen days, and ran through a whole stable in about three weeks.

The disease in question differs then from glanders, more particularly in the character and distribution of the ulcers; also in the absence of lymphatic inflammation; in the quickness with which the ulcers healed; in the non-appearance of ulcers in the Schneiderian membrane; further, in the rapid course of the disease, its short incubative period, and the quickness with which it spread from one animal to another.

The virus seems to lose its virulence after passing through the system of several animals. From the scarcity of horses the experimentalists had to use cattle, when by degrees the lymph lost its infectious properties, until it finally ceased altogether. This characteristic separates the disease from variola, which it otherwise closely resembles.
CHAPTER XXIII.
CONTAGIOUS DISEASES—continued.
MALADIE DU COIT.¹

The name maladie du coit gives no further idea of the disease than that it results from the act of copulation. Other and various denominations, however, have been offered as expressing more definitely the character of this affection, some having been founded on its supposed analogy with the syphilis of the human being, and others upon the predominance of certain symptoms which have most particularly struck the observers.

Among these designations are the following:—Syphilis du cheval (syphilis of the horse); vérole; typhus vénérien; maladie pustuleuse et chancreuse maligne (frambésia morbus pustulosus) (Erdley); épizootie chancreuse (Hering); maladie vénérienne du cheval; contagious eczema; paralytic disease of the horse; epizootic paralysis; epizootic paraplegia (Signol), &c.

As all these terms and many others of a similar nature imply mistaken conceptions of the observers who so designated the disease, they have therefore been discarded, and the simple name maladie du coit, which (as I have said) is merely expressive of the fact that it is contracted during copulation, has been retained. It is difficult to give a correct definition to this affection, the nature of which is not thoroughly understood, as may be seen from the following translation.

The nature of the disease is not plainly revealed by the symptoms and pathological changes. Some authors call it a nervous disease, and others rank it among the diseases of the generative apparatus.

¹ I am indebted to Mr. Archibald Robinson, M.R.C.V.S., Greenock, for much valuable assistance in preparing this chapter.
MALADIE DU COIT.

It can scarcely be considered as vaginitis, nephritis, or angiitis. Though it is true that the symptoms and pathological anatomy show that these conditions exist, it must be remembered that they are consecutive, and that they do not form the base of the affection; also, that it is not limited to such organs as the vagina, the kidneys, the spinal cord, &c. &c.; for were it thus, according to the description of the disease, its nature would be seen to change too often.

It has been ranked in the order of inflammatory diseases, but it is quite different from them. In the inflammations, the circulation becomes accelerated, and the plasticity of the blood augments; while in this affection, on the contrary, the pulse is slow, the blood less plastic, there is a collapse of the vessels and non-turgescence; consequently no analogy exists between these two conditions. Not only is the blood less plastic, but greatly altered in its physical properties and constituent principles. It is black, no longer coagulates, assumes the consistence of gooseberry jelly; in a word, has lost its vital and exciting properties, qualities indispensable to the free discharge of the nutritive functions. It presents characters identical with those of epidemic typhoid affections. Such at least is the opinion of the Commission at Tarbes.

The Germans, struck by the nervous symptoms which show themselves in the later stages of the disease, have considered it a nervous affection, and as it is nearly always accompanied by alterations of the lymphatic system, they have called it lymphatic—nervous—cachexia.

Others have looked upon it as a scrofulous, a nervous-phthisic, or scorbutic affection.

Its syphilitic nature has been admitted and rejected; admitted on account of the analogy of some local symptoms, and rejected on account of the non-transmissibility of syphilis from man to the horse by inoculation, and of the inefficacy of mercurial preparations in its treatment.—(M. REYNAL, Traité de la Police Sanitaire.)

It may, however, be defined as a specific blood disease, characterised in the early stages by morbid changes in the urino-genital organs.
SYMPTOMS.

As the disease manifests itself in two forms, benign and malignant, I will first detail the symptoms of the benign form in the female.

**Benign form.**—The first symptoms of the benign form in the mare are often so slight that they do not attract the attention of the owner. They generally appear in from twenty-four hours to a fortnight after copulation. The animal strikes the ground several times in succession with its hind feet, whisks its tail, urinates frequently and in small quantities; in fact, the symptoms are those presented by this animal at the period of oestrus. There is, however, this difference, that no matter how often the mare is covered, the sexual appetite does not appear to be satisfied.

The first local symptoms observable are a redness of the vaginal mucous membrane and the discharge of a mucous-purulent fluid. At first this discharge is very slight; soon, however, the mucous membrane and the lips of the vulva become infiltrated, the discharge increases, at the same time becoming thick, viscid, and of a whitish-yellow colour, coagulating around the vaginal orifice, and on the tail, perineum, or other external parts with which it may come in contact.

On the mucous membrane of the vagina may now be observed (though not invariably) a number of small pustules, about the size of a millet seed, changing into superficial ulcers, which heal rapidly and are replaced by others, that, like the first, are generally most abundant in the fossae navicularis, and on the clitoris.

According to M. Roll of Vienna (quoting from Marech), during the prevalence of the *maladie du coit* in Bohemia, vessels of various sizes, containing a yellowish fluid, were observed on the mucous membrane of the vagina, instead of the pustules just mentioned.¹

The general symptoms are oedematous swelling of the abdomen,

---

¹ M. Rodloff says that the form designated benign by the authors is quite a distinct disease, and that the exanthematos condition, when found associated with what has been termed the malignant form, is accidental. Thus, what others call the benign form of the *maladie du coit*, he calls "exanthéme cutané," while to the malignant form he gives the name *maladie du coit*. (Vernay's Translation.)
perineum, and extremities, wasting, general weakness, and a slight engorgement of the submaxillary glands. The circulation, respiration, and even appetite remain unaltered in this form; the last may, however, become capricious. At this stage the symptoms commence gradually to diminish, and the disease usually disappears of itself in from a fortnight to two months. The only trace of it that can be seen four or five months afterwards is a slight thickening of the mucous membrane of the vagina, and that only in some cases.

It should, however, be remarked that this form may become aggravated and assume the malignant one.

In the stallion the benign form is difficult to detect. A considerable time may elapse before the manifestation of any symptom, and even then an intermittent edematous engorgement of the sheath may be the only one apparent.

The benign form in the stallion may become malignant as in the mare.—(Reynal.)

Malignant form.—The local symptoms of this form in the mare are exactly the same at the onset as those of the benign form. Soon, however, they become more pronounced.

The lips of the vulva augment and diminish alternately; or one side only may be swollen, thus giving the organ a deformed appearance. Generally the swellings extend to the anus, and along the perineum to the mammary gland. The mucous membrane of the vagina presents numerous furrows, becomes still more infiltrated, and is studded with numerous patches of a blue or yellow colour, and on it may now be seen the pustules spoken of in the benign form.

The temperature of the vagina is elevated; the liquid that flows from it is more abundant, and also more irritating than in the preceding form, exorciating and denuding the skin of the thighs, &c., over which it trickles.

On the external surface of the lips of the vulva, on the perineum, and on the inside of the thighs, lenticular pustules, which dry and form scabs, are sometimes seen. When these scabs fall they leave circular wounds, which heal rapidly.

The vulva and the mucous membrane of the vagina are now of a doughy consistence, and the latter presents a marbled appearance, the clitoris becomes swollen and indurated, and protrudes from the inferior commissure. The discharge is thick
and purulent, of a reddish or greenish yellow colour, and exhales a very disagreeable odour.

The animal urinates often, and in small quantities, the evacuation being preceded, accompanied, or followed by a more abundant flow of the purulent discharge.

The ejection of the urine causes a great amount of irritation, and if the animal encounters any resisting obstacle behind her, she will rub herself violently against it.

Mares in foal generally abort about the third month. When they carry the full period, the foals to which they give birth are usually dead, or die in a few hours.

_Stallion._—The manifestations of the symptoms in the stallion are exceedingly uncertain. Sometimes they remain latent for a very long period, and are only aroused by a repetition of the coit.

The sheath then becomes the seat of an oedematous swelling, extending in front to the umbilicus, and occasionally to the sternum, and behind to the scrotum, which may either retain its normal proportions or become slightly involved in the swelling.

According to M. Reynal, stallions have been observed to present no other symptoms than a swelling of the sheath for eight, ten, or even twelve months, and still they were affected by the disease.

In some cases the testicles, as far as external manipulation can decide, remain perfectly healthy; in others they become swollen, and the animal evinces great pain on the slightest pressure.

When the penis is protruded it may present no alteration, or it may (if destitute of pigment) have a reddish or marbled appearance. In some cases spots of various diameters, and of a deep violet colour, resembling ecchymosis, have been observed. When the organ is in a state of complete erection the glans penis acquires a volume so great that its return is accomplished with considerable difficulty. There is a hypersecretion of the urethral mucous membrane, which protrudes slightly from the meatus urinarius, attains a somewhat globular form, and a crimson or yellow colour.

Cicatrices have been observed on the penis, in greatest quantity near the glans, and the observers have thought it probable that they were the result of the healing of small super-
ficial ulcers, caused by the destruction of vesicles which had formed on this organ.

After each evacuation of urine, effected after a number of painful efforts, and expelled in a small but continuous jet, the animal stamps violently, and whisks its tail, as if the passage of that fluid through the urethra had caused a considerable amount of pain.

In concluding the local symptoms, it may be remarked that paraphymosis is not an unfrequent result of the local swellings.

**GENERAL SYMPTOMS.**

As these are the same in both sexes, it would be useless to consider them separately.

A more or less abundant discharge of a muco-purulent matter from the nostrils, and of tears from the eyes, sufficiently indicate that there is a general affection of the mucous membranes, of which these visible are highly injected.

The lymphatic ganglia, not only in the vicinity, but also those in the submaxillary space, are engorged.

The appetite is generally good, and the food thoroughly digested; nevertheless the animal gradually falls off in condition, and, to use a common expression, becomes hide-bound, with a dry and staring coat; the perspiration gives off a most offensive odour.

The sensibility of the lumbar region is so great that in some cases ordinary pressure will almost bring the sufferer to the ground. The presence of albumen has been observed in the urine.

General weakness soon manifests itself by the weight of the hind quarters being thrown alternately and incessantly from one posterior extremity to the other.

When the animal is caused to walk the gait is very uncertain, and the sudden flexion of the joints is sometimes so great as to cause it to fall. There is a considerable tumefaction around the larger joints, and especially around that of the haunch. This tumefaction is very painful, and causes the animal while at rest to lift its leg with a sudden jerk, after the manner in which a horse with stringhalt behaves when caused to move suddenly, but it places it more carefully on the ground again than does the latter. When both limbs are affected, this movement is manifested alternately. These symptoms of lameness are some-
times intermittent, disappearing for a week or two, and then reappearing with a greater intensity.

After some time the appetite becomes exceedingly capricious, but is never entirely lost, the animal continuing in many cases to eat till within an hour of its death.

One or both hind extremities now become paralyzed, causing the sufferer to fall upon its litter, and the entire muscular system becomes atrophied, but more especially the hind quarters and legs.

The mucous membrane of the nose becomes of a yellow and the buccal membrane of a leaden colour; and there may be slight constipations.

Unless pneumonia or other complications of the respiratory organs set in, the respiration remains natural. M. Rodloff has often observed horses suffering from this disease become broken-winded.

In the mare, one or other half of the mammary gland sometimes becomes the seat of an inflammation, which usually terminates in suppuration.

In the incubative stage of the disease, numerous cutaneous tumours form, which, unlike those of farcy, are entirely situated in the skin, and do not invade the subcutaneous tissues. They are of various sizes, but may be divided into three—a small, a medium, and a large size.

The small tumours, which appear suddenly, and may as suddenly disappear, have attained, when first seen, their full dimensions. This, however, is not absolutely without exception, as in some instances an increase of circumference has been observed. The middle and large-sized tumours commence by a circle, on which the hairs stand; the centre of the circle gradually fills in, and the tumour becomes fully developed within twenty-four hours. Their duration is variable, but may be said to be from four to nine days. The disappearance of the small tumours may be effected in a night, while that of the larger ones takes place more gradually; temperature and sensibility in the former are not above that of surrounding parts, while in the latter both are considerably exalted. Their disappearance is soon followed by the eruption of a fresh crop, which may be situated on the same or on different parts of the body.—(M. RODLOFF.)

1 Translated by M. Verheyen for the Recueil de Médecine Vétérinaire, 1855.
The paraplegia, which almost invariably sets in before the termination of the disease, and which is described by some authors as its third stage, is occasionally accompanied by other paralysis, such as that of the lips.

Glanders and farcy are not unfrequent terminations.

PROGRESS AND DURATION.

The progress of the disease is slow; it does not terminate before three or four months at least, and it may extend over a much longer period. An apparent recovery should always be looked on with suspicion, as the affection is subject to intermissions. When the disease exists in a country, all stallions presenting persistent swellings of the sheath from unknown causes should be regarded as suspicious, and if in use as reproducers, their work in that sphere should be prohibited, for, although latent, the disease is none the less contagious.—(M. Reynd.)

Its duration is variable, extending from three to eight months, and even to three years.

A Ministerial Order in Prussia prohibits the removal or use, as reproducers, of affected stallions, and in the case of recovery they are not declared healthy until after the lapse of three years.

ETIOLOGY.

The original cause has been until now, and is likely to remain, in obscurity. A great many hypotheses, however, have been raised, and M. Lafose, in his pathological treatise, gives a long dissertation on the effects produced by the crossing of various breeds, the change of climate necessitated for that purpose, the changeable condition of the atmosphere during the period at which the disease makes its appearance, which is always in spring, &c. &c. These, he says, are the predisposing causes, while copulation, too often repeated, by over-exciting the genital organs, and perverting the secretions of the parts which become primarily affected, is the exciting cause.

This theory of M. Lafose is, however, open to grave objections. If it be correct, why does not the disease appear every year and in every country in which the animals are exposed to the same causes?
The supposition that the maladie du coït has been transmitted from man to the equine race, has not been rejected on account of the revulsion of feeling to which the thought of such a degradation gives rise, for the record of the debaucheries of Rome sufficiently show that sexual intercourse between man and the inferior animals has taken place. Even in this enlightened age the Arabs believe that by fornicating with the ass they can rid themselves of venereal diseases, and on this account some of the adherents of its syphilitic nature have founded the origin of this disease.

Its syphilitic nature, however, is rejected on better grounds. The symptoms are not those of syphilis; the indurated chancre, or the ulcerations which invade the throat, lips, &c., that characterise this disease in man, are not met with in the maladie du coït.

The inoculation of the syphilitic virus to the lower animals, as shown by numerous experimentalists, and more especially by the carefully conducted experiments of M. le Docteur M. A. Horand (Chirurgien en chef de l'Antiquaille à Lyons), and M. F. Peuch (Chef de service de clinique à l'école vétérinaire de Lyons), practised in 1868 and 1869, and published in 1870, is followed by entirely negative results. The mercurial treatment, so efficacious in syphilis, is not only entirely fruitless, but has been thought to hurry the death of the equine sufferer.

It would be useless to detail the hypotheses of the various authors, as they are all equally unsatisfactory.

The history of the disease, if minutely related, would occupy several pages. I will, however, limit myself to say that it was not known until the end of the last century, when it was first seen in Russia (in 1796), and that it has since invaded Africa, Egypt, and the majority of the European countries. No mention, however, has been made of it in Great Britain, Spain, or Belgium.

CONTAGION.

The contagious properties of the disease have been denied by some, but the experiments of M. Lefosse are sufficient to convince the most incredulous. In 1852 that gentleman took fifteen healthy mares from a regiment stationed at Toulouse (where the disease had never been seen, and where it has never since
reappeared), and presented them to affected stallions which had been brought for the purpose from the Dépôts de Tarbes, where the disease was then raging. Five of these mares became affected to a slight degree, the disease disappearing spontaneously. Five others became seriously affected, one of which only recovered; thus showing that five only entirely resisted, while four succumbed to the disease.

Other experiments could be related, but I think the above is quite sufficient to show that its transmission during the act of copulation is undeniable.

It is, however, just to observe that numerous experiments by inoculation were conducted without result, before the contagion was denied.

M. Hering, notwithstanding, succeeded in one instance in producing the disease by rubbing the mucous membrane of the vagina with the virulent matter.

It is worthy of remark that stallions offer more resistance to the contagion than mares.—(M. REYNAL.)

**POST MORTEM APPEARANCES.**

The _post mortem_ appearances with regard to the genital organs do not coincide in different subjects. The lesions of the external organs and of the mucous membrane are, however, constant.

The sheath, when cut into, presents the appearance of a hard, homogeneous, yellow tissue, but on a closer examination the fibres of the areolar tissue may be distinguished, and between them the serosity which gives the appearance indicated.

The penis is partly protruded from the sheath, and slightly infiltrated towards its free extremity. On its external surface, though very rarely, small whitish elevations, formed by the infiltration of a small quantity of serum under the epithelium, have been observed. Small dried coagula of blood, which give the ecchymosed appearance mentioned in the symptoms, have also been encountered; but the mucous membrane offers no other alterations than a slight protrusion, a thickening, and a yellowness in colour.

The mucous membrane of the vesiculae seminales is said by some to offer a red or violet appearance, containing a yellowish thick matter of a purulent aspect; by others, the vesiculae semi-
nales, as well as Cowper's and the prostate glands, are said to be in a normal condition.

The testicles may either be healthy, atrophied, or hypertrophied. When hypertrophied a yellowish serosity is found in their interior. In the mare the mucous membrane of the uterus and vagina is thickened, ecchymosed, and of a reddish-brown colour. In the uterus a muco-purulent, yellowish-white, or a chocolate coloured fluid, analogous to that which flows from the vagina during the course of the disease, is found in greater or less quantity. It is said to have been so abundant in some cases as to have given the patient the appearance of being pretty far advanced in gestation.

The kidneys may be in the normal condition or they may be hypertrophied. Their pelves contain a substance resembling the white of an egg, which has been found to be abundant in albumen. M. Lahoche has found them to contain in exceptional cases a substance similar in appearance and consistence to honey.

The mucous membrane of the ureters and bladder in both sexes present a similar aspect to that of the womb in the female.

The muscles are friable, as are also the bones, especially the femur and ribs, of which the spongy tissue is generally impregnated with a dark-coloured blood, or with a yellow gelatinous matter.

The coxo-femoral and pubio-femoral ligaments are red, thickened, softened, and sometimes ruptured.

The synovia of the articulations is abundant, muddy, and presents the colour of blood.

The cartilages are yellow and soft, and have sometimes disappeared from the articular surfaces.

The fatty matter has everywhere disappeared.

The subglossal, sublumbar, and mesenteric ganglia, as also those in the vicinity of the urino-genital organs, are considerably enlarged, and of a yellow or reddish-brown colour. They are sometimes found to contain purulent matter. The French authors describe no other lesions in the cranial cavity than the super-abundance of the subarachnoid fluid, while the German authors affirm that the brain is in a degenerated state. They, however, agree that in some cases the spinal cord is softened, particularly in the lumbar region. It may, however, be re-
marked that when the disease terminates in paraplegia, if this condition of the cord be not found, it is at least slightly congested.

Occasionally the volume of the sacro-lumbar plexus and sciatic nerves is augmented by a serous infiltration.

The digestive organs are healthy; in some instances, however, the liver and spleen are enlarged and softened.

The lungs are healthy (unless the disease has become complicated by pulmonary affections), but the mucous membrane of the bronchial tubes and larynx is slightly affected.

The sinuses of the head often contain a yellowish, oily matter, and the Schneiderian membrane is of a leaden colour, with red spots scattered over its surface.

The muscular tissue of the heart, like the rest of the muscles, is soft, friable, and of a pale yellow colour.

The blood is very much altered; it is fluid, deficient in fibrin, and, according to M. Lafosse, who has made microscopical examinations of it, the coloured corpuscles present a deformed appearance.

**TREATMENT.**

Antiphlogistics (including bleeding), emollients, tonics, stimulants, alteratives, &c. &c., have all been employed in this disease, but with so little success, that until the appearance (in 1865) of M. Trelut's memoir it was believed incurable.

M. Trelut, after a careful study of the disorders produced in the organism by the *maladie du coït*, adopted an entirely different treatment, the efficacy of which is beyond a doubt.

Being struck by the fact that the blood of animals suffering from the disease was deficient in one of its most important elements, viz., the fibrin, he thought that if this constituent were renewed in the vital fluid the disease might be overcome.

He accordingly procured the necessary fibrin by stirring the blood of cattle when warm, thus separating the fibrin from the other constituents. The fibrin obtained in this manner was dried in an iron pot, in which a little butter had been melted to prevent carbonization; it was then divided into small particles and administered in the morning, fasting, in doses of sixty grammes (3xv.), either as an electuary, or added to half a quart of gruel as a drench. To stimulate digestion twenty or thirty grammes (3v. or 3viis.) of turpentine were administered every second
morning with the drench. From 3i. to 3ij. of iron, reduced by hydrogen, alternated with from fifteen to thirty grains of the white oxide of arsenic, were also given, and food of the most substantial kind was allowed.

As the patients under the charge of M. Trelut increased, he found that a sufficient quantity of fibrin could not be obtained in the manner described. He then substituted for the pure fibrin of the blood of cattle, cooked horse flesh, very finely divided, and administered in the water which had served to cook it. When the bouillon was finished the flesh was mixed with honey and given as a electuary. Were it not important to utilise the soup, says M. Trelut, the flesh could always be given most conveniently in the latter manner.

The flesh was administered in doses of from 100 to 150 grammes.

When paralysis set in, cantharidine liniments, followed by mustard poultices, were applied to the abdomen; and as soon as an abundant effusion had been established, the pointed firing-iron was applied, penetrating as deeply as possible, in order to fix the engorgement. After the establishment of this engorgement the paralysis became gradually ameliorated, and in twenty-four hours, the animal, which was helplessly stretched upon its litter, was able to regain its feet without assistance.

The internal treatment requires to be continued at least forty-five and at most 145 days, and on an average from two to three months.

By this treatment M. Trelut was successful in sixteen cases (in which the patients were seriously affected) out of seventeen.

The seventeenth was a mare which aborted, and the lesions ofmetro-peritonitis found at the autopsy would have been sufficient to account for her death.—(Memoire sur la Maladie dite du Cott, par M. Trelut, Recueil de Medecine Vétérinaire, Janvier 1865.)

Local treatment.—In stallions, during the first stage, or that in which the disease is confined to the genital organs, good results have been obtained from castration; but although this operation seems to check the course of the affection, it does not eradicate it.

In the mare, mucilaginous injections, followed, later on, by mild astringents, and still later, if necessary, by the sulphate of copper, sulphate of zinc, or nitrate of silver, &c., have been recommended.
CHAPTER XXIV.

CONTAGIOUS DISEASES—continued.

CANINE DISTEMPER.

Definition.—A febrile disease, due to the operation of a morbid poison; occurring spontaneously from ordinary causes of disease, or as the result of contagion and infection, and known in almost all parts of the world.

PATHOLOGY.

The virus primarily induces a febrile condition of the system, and specifically affects the mucous membranes of the nose and eyes. In some cases the poison destroys by shock, the animal dying, in a few hours, from collapse, without any true signs of distemper being developed. In other cases the action of the poison is concentrated upon the nervous system, causing epileptic fits, spasms of various muscles, and finally coma and death. Again, the liver seems to be the organ chiefly affected, and in other instances the intestinal canal or the bronchial mucous membrane is the seat of the local effects of the virus. Secondarily, the spinal cord or some of the spinal nerves become diseased, and, consequently, distemper often terminates in paralysis of the posterior extremities, or in chorea; the clonic spasm characteristic of chorea being generally more observable in the muscles of the neck and fore extremities. In consequence of the variety of forms which the malady assumes, it has been described as five different diseases, namely—(1.) The catarrhal: (2.) The respiratory or bronchial: (3.) The bilious: (4.) The intestinal: and (5.) The nervous. These are merely varieties of one and the same disease, and exemplify in a most remarkable manner the method in which the same virus or poison may act
upon more parts or organs than one, as is the case with various medicinal and other agents.

The spasmodic condition of the body—the chorea—and the paralysis also illustrate how a morbid poison, after exhausting its powers upon one or more organs, may, after a space of time, affect other organs of the same body.

Distemper, like all contagious and infectious diseases, has an uncertain but short period of latency. It affects the system only once, and sometimes prevails as an epizootic.

Some writers have compared distemper to the typhoid fever of man. I have carefully dissected numerous fatal cases of distemper, and looked particularly for the specific lesion of typhoid, namely, congestion and tumefaction of Peyer's glands, but have failed to detect any growth in the gland cells of the intestines. In the intestinal form of the disease a generally congested condition, with even ulceration of the mucous membrane, may be witnessed, but these alterations are very different to those observed in typhoid fever. Again, intestinal lesions are the specific distinctions of typhoid, whereas in distemper inflammation of the mucous membrane of the bowels is only seen in that form in which the virus seems to exert its influence on that part of the animal body, and it is only in a minority of instances that this effect is witnessed.

I can compare distemper to no human disease except measles, and the points of analogy are very great. In both diseases catarrhal symptoms are manifested; they are infectious diseases; they generally occur but once in a lifetime; they chiefly affect the young; in almost all cases of distemper there is some cutaneous eruption or rash, and desquamation of the cuticle; catarrhal ophthalmia, bronchial and pulmonary inflammation, and dysentery, are complications of both diseases, and, finally, convulsions sometimes occur both at the commencement and during the progress of measles and of distemper.

I am not aware, however, that measles is succeeded by either paralysis or chorea; nor do I mean it to be understood that distemper is communicable to man.

SYMPTOMS.

The primary symptoms are those of fever, associated with those of catarrh. The dog shivers, is dull, restless, with dry nose and
injected eye. The appetite is partially lost; there is thirst and rapid loss of flesh and condition; the urine is high-coloured and scanty; the bowels are generally irregular, sometimes constipated, sometimes looser than natural; the faces are dark-coloured and fetid. In the course of a few days the catarrhal symptoms, which at first may have been limited to frequent sneezing, with a slight discharge from the nose and eyes, are fully confirmed. The nasal discharge is now more or less profuse; the eyes are weak, occasionally inflamed, and discharge tears and mucus. Very often the eyelids will be gummed together, and the animal thus rendered temporarily blind. Cough is present, at first dry and husky, afterwards moist. The breathing is sometimes much quickened, and the cough dry and painful, showing that the lung tissue and pleura are affected: the pulse may range from 120 to 150 beats per minute, and the temperature is increased. In other cases the respiratory movements are but little affected, except when the bronchial tubes are filled with mucus, which is coughed up, and the breathing becomes much relieved. As the disease advances, debility rapidly increases, the dog being often at the end of the first week scarcely able to stand; the appetite becomes more and more impaired, and the digestive powers much debilitated. Food now partaken of or forced upon the animal is quickly ejected by vomiting, or passes through the intestinal canal in a fetid, ill-digested condition. At the end of about a fortnight these symptoms may abate in intensity, and the dog slowly regain its strength. Very commonly, however, complications occur which tend towards a fatal termination. The complications are as follows:—

1st. Pneumonia.—The breathing becomes laboured, rapid, and panting; the prostration of strength is very great; the dog is unconscious of surrounding objects; the pulse is frequent, feeble, and intermitting, and the feet, nose, and ears are icy cold. If the ear be applied to the chest the crepitating sounds of pneumonia will be detected.

2d. Jaundice.—This occurs from the presence of a blood poison, interfering with the normal metamorphosis of bile, from congestion of the liver, or most commonly from catarrhal inflammation of the mucous membrane of the biliary ducts; the swollen mucous membrane mechanically blocking up the tubes, and thus impeding the flow of bile.—(See Liver Diseases.)
3d. Intestinal complications.—Vomiting and purging are prominent symptoms. Sometimes there is true dysentery, the feces being tinged with blood; tympanitis and abdominal pain.

4th. Epileptic fits.—Spasmodic convulsions of varying intensity, coma and paralysis, more or less complete, occur as primary symptoms. These are to be separated from those signs of nervous alterations which occur as secondary affections in distemper. In the first case the brain and nervous symptoms are concomitant with or shortly succeed the attack; whilst in the latter, chorea, paralysis, or complete coma appear after the febrile condition has more or less abated, and when the dog seems in a fair way to recover.

Conjunctivitis is not at all an uncommon complication, and ulceration of the cornea, perhaps unprecedented by any inflammatory signs, may occur from mal-nutrition.

In other cases cellulitis or an erysipelas-like inflammation of the extremities occurs, the inflammation sometimes suppurating in various parts: the suppuration, being of a diffuse or infiltrating character, causes much pain and rapid exhaustion.

In most instances some cutaneous eruptions are seen on the inner surfaces of the thighs and other parts, where the hair is thin and downy; the eruptions at first resemble flea-bites, but may become vesicular or even pustular; the skin is harsh, and much epithelium is thrown off, causing the hair to be filled with scales of scurf.

There are various conditions of the body which predispose the disease to attack the dog in the various ways above enumerated. The presence of worms in the intestinal canal may excite the intestinal form; previous high feeding and obesity the bilious; and the eccentric irritation of the nervous system caused by teething, worms, &c., predispose the dog to the nervous form.

Distemper originates undoubtedly from contagion as well as from atmospheric influences, and usually rages as an epizootic. The majority of dogs in some districts suffer from the disease, whilst in other parts of the country it is scarcely ever heard of, unless brought there by a dog already diseased. High-bred dogs are more susceptible to distemper than those of a lower breed, but no class of dog is exempt. During the author’s residence in Australia the disease was imported from Europe, and scarcely a dog in the colony of Victoria was unattacked. Nor were the
wild dogs allowed to escape; hundreds of these were to be seen lying dead in the bush in various parts.

The contagium or virus, probably a microbe which may yet be attenuated and applied for the purpose of protective inoculation, will taint a kennel for a long time after the disease has disappeared; and it is always unsafe to introduce fresh dogs into such a kennel, if it cannot be proved they have passed through the disease, unless the walls, drains, fittings, &c. are thoroughly cleansed and disinfected.

**TREATMENT.**

In the treatment of distemper it must always be remembered that the disease runs a certain but indefinite course, and that all the symptoms are but the result of the operation of a morbid material existing in the blood. If these facts be borne in mind, the practitioner is not likely to resort to those dangerous and exhausting remedies so generally recommended by writers on canine diseases. The administration of calomel, jalap, aloes, tartar emetic, digitalis, with the application of blisters or setons, is calculated at all times to do harm.

In the earlier stages, if the bowels are at all irregular, a small dose of castor oil is to be prescribed. The dose must vary in strength according to the size and age of the dog; from a teaspoonful for a small dog or young puppy, to an ounce for a well-grown dog. This will remove any ill-digested or indigestible material from the intestinal canal.

After the laxative has operated, I have found from two to six grain doses of the hyposulphite of soda useful, modifying the symptoms most materially, and converting what has threatened to be a serious case into a mild attack. Care must always be taken not to administer any medicine in such large doses as to disorder the stomach in any way, or to cause vomiting, as it is of essential importance to keep up the animal strength by proper food, *spontaneously portaken of.* If there be much prostration of strength, a tea-spoonful of good sherry, or one dram of spirits of nitrous ether, may be administered three or four times a day, in addition to the hyposulphite, with very great advantage.

This simple treatment, in addition to warmth, fresh air, a clean bed, and clothing for thin-haired dogs, with a plentiful supply of fresh cold water (or milk and water if the dog will take it) for the animal to drink, sponging of the nose and eyes
not being forgotten, will often be successful. The food must be
restricted in quantity, and of an easily digested nature. In
my own practice I find porridge and milk to be the best, pro-
pvided the dog will take it; but if it be a pet dog, and used
to pampering, it must have what food it will eat, and what
it has been used to, in modified quantities. It may be laid
down as a rule that the digestion of what the dog is fondest
of will be more easily performed, provided that it is not
allowed to eat too much. After the disease has continued for
six or seven days, small doses—from one grain to three—of
quinine may be administered, care being taken to discontinue it
if it seem to disagree with the dog.

If there be much irritation of the stomach and vomiting,
hydrocyanic acid, from two to four drops, Scheele's strength, will
have a calmative effect on the gastric organs and allay the
vomiting. Purging, if not excessive, should not be violently
checked, but should the dog seem to lose strength from this cause,
chalk may be first tried, and afterwards tincture of opium, from
ten to twenty drops, three times a day.

The pulmonary complications are best relieved by the applica-
tion of hot flannels to the sides, or hot fomentations may be
substituted in smooth-haired dogs. In rough-haired ones, the
hair saturated with the wet is a long time in drying, and the
animal is apt to take cold. Nitrate of potash may be dissolved
in the dog's drinking water, or given in solution in from six to
twenty grain doses, as a febrifuge and diuretic; and the chloral
hydrate may be given at night, particularly if the dog is sleep-
less. The nervous symptoms may depend upon reflex irrita-
tion. If from teething, the gums are to be lanced. If from the
presence of worms, and this is a common cause, and tape-worm
the parasite generally met with, from one scruple to one drachm
of areca-nut is to be administered. If the appetite is entirely
lost, advantage must be taken of the thirst, and beef tea or milk
allowed the dog to drink. If it will not drink spontaneously,
nourishment must be forced upon it, in small quantities and
oft repeated. A raw egg beaten up with a glass of sherry, care-
fully administered, will be of great service; in other cases,
brandy and beef tea. I am, however, opposed, unless the pro-
stration of strength threatens to prove rapidly fatal, to the forcing
of large doses of stimulants, as they often cause much mischief,
careful nursing and good attendance being much more beneficial than any mere medicinal remedy,

I have very little to say upon the treatment of the secondary nervous complications. They are due to a variety of pathological changes.

Paralysis sometimes results from obliteration or plugging of the spinal veins, which are found enlarged and pressing upon the cord: I have found this in several dissections of dogs which had died or had been destroyed whilst suffering from paralysis—from atrophy of the cord, the nervous matter of which being in some instances replaced by a semi-fluid deposit, and from congestion and disintegration of its substance.

Some cases of paralysis after distemper, if kept long enough and well fed, will recover. As a rule, however, the loss of power remains, and the dog has ultimately to be destroyed. I have tried strychnia and other nervine tonics, but cannot say that they do much good. Iodide of potassium—given on the assumption that the paralysis resulted from the pressure of an exudate on the cord—has been tried also by me, but with no very successful results. Blisters to the spine, setons, and even the application of the actual cautery, have also been tried in such cases. Such treatment inflicts much pain on the poor patient, but does not remove the disease or prolong life.
CHAPTER XXV.

CONTAGIOUS DISEASES—continued.

ANTHRAX AND ANTHRACOID DISEASES.

Anthrax; charbon; gloss-anthrax; apoplexia splenectica; carbunculo contagiosa, &c. (L.); charbon; chancre à la langue; mal de sang; sang de rate; typhomiè; fièvre putride, &c. (F.); milzbrand; milzbrand-fieber; petechial typhus; pestfieber (G.); carbone; febbre carbonculara, &c. (L.); black-leg; quarter-ill; apoplexy of the spleen; malignant sore throat; known in India as Loochiana disease, and in South Africa as horse sickness; in sheep as splenic apoplexy; in America, splenic fever, Texan fever, trembles, &c.

The term charbon is applied by the French veterinarians for the reason that the regions of the body where the disease is localized are coloured black. Anthrax (a burning coal) is now adopted by most writers as a generic term, and applied to what is otherwise known as splenic fever, but it throws no light on the nature of the disease, as others, septic and putrefactive in their nature, present a similar appearance of the blood.

Definition.—The disease consists in a special and primitive alteration in the blood, in which an organism termed the Bacillus anthracis is rapidly developed and propagated, and is more special to the herbivora and birds. Inoculation with the blood or tissue of animals which have died from it, induces, both in man and other animals, a malignant form of inflammation called "malignant pustule." For this reason anthrax is looked upon, and described, as a truly contagious disease.

Anthrax appears at all seasons, but principally in the spring or during summer and autumn. It occurs either as a sporadic, enzootic, or epizootic disease, attacking animals of any age—the fat, vigorous, plethoric, as well as the lean, feeble, and languid.
It is a remarkable fact that wounds, simple in themselves, in cattle subjected to the influence causing charbon, although not suffering from it, often become mortal.

HISTORY.

Anthrax has a very ancient history, and was known in Asia Minor at the period of the siege of Troy; but, leaving ancient history aside, it may be useful to mention that the seventeenth and eighteenth centuries were remarkable for the devastations committed by various epizootic outbreaks of anthrax. In 1617 it was prevalent and of such a fatal nature in the neighbourhood of Naples, that over 60,000 persons perished through partaking of the flesh of animals which had died of the disease. In 1731 it declared itself in several provinces of France, notably in Auvergne, Bourbonnais, and in Languedoc, where it was studied by Sauvages, and described by him under the term glossanthrax.—(Nomenclature Methodica, vol. ii. page 360.)

1767, 1768, 1775, 1779, 1780, and 1800.—These years were signalized by a charbonous malady which extended nearly all over France, and affected all the domesticated animals. The disease was studied by Bourgelat, Chabert, Berdin, Huyard, Desplas, Detil, Gordine, Gilbert, and a great number of veterinarians. From 1800 to 1846 many outbreaks of charbonous disease were observed, generally in the hottest months. They were studied by Demoussy, Sansol, Pradal, D'Arboval, Mathieu, and others. During more recent periods, outbreaks have been studied by Roche-Lubin in Avignon; by M. Rey on the heights of the Alps; and in Eure et Loire by the Medical Society of the department; and by MM. Renault and Delafond, who were sent by the French Government, the one to Allier and Nièvre, and the other to Somme, to report on the disease. Within recent years the disease has been profoundly studied by Pasteur, Chauveau, and Koch, and others in France and Germany. In this country, however, little has been done for its elucidation; and though less frequent here than on the Continent, it is, however, quite as fatal in its character.

ETIOLOGY.

The influences which predispose to the development of anthrax are arranged by French veterinary writers under four
principal heads, comprising respectively the influences of
temperature; water spread over the surface of the earth, as in
morasses and stagnant ditches; forage tainted with decomposing
animal and vegetable matters; and contagion.

Influence of temperature.—The hygrometric and thermometric
conditions of the atmosphere, which always exercise a marked
action on the organism, disposing it under certain circumstances
to anthrax, are stated by several authors to be those charac-
terised by humid and persistent fogs, coldness, and humidity;
a tempestuous atmosphere; alternations of burning heats and
stormy rains.

It rages as an enzootic on the borders of rivers, and in low
lands which have been inundated. In the months of July and
August, signalized by excessive heat, charbon has been frequent.
The years 1712, 1731, 1775, 1779, 1780, 1823, 1824, 1825,
1846, have furnished memorable examples. Under the influence
of excessive and prolonged heat, the rivers, ponds, brooks, &c.
were dried up, the soil opened in crevasses, and the disease was
developed to an enormous extent. In France it is stated that
a very warm summer is never seen without charbonous diseases
being prevalent; and it is concluded that a high temperature,
especially if preceded by a damp or moist atmosphere, is very
favourable to the development of charbon.

Influence of ponds, morasses, and stagnant waters.—The history
of the malady demonstrates that morasses are favourable to its
development, as it is observed that it is frequent in countries
where they occupy a large surface. It is also frequent in
countries exposed to inundations, and where water stagnates
on the surface of the soil; and where animals are made to
stand in mosses and stagnant waters, the malady commits great
ravages. This fact is remarkable, not only in France, but in
other countries.

Observers who have closely watched these affections in this
country, where it seldom appears spontaneously in the horse,
almost unanimously conclude that in cattle and sheep they are
due to dietetic errors; more particularly to sudden and violent
changes in diet, whether that change be from a poor to a highly
nutritious, more particularly a nitrogenous diet; from dry and
good food to watery unripe provender; to damaged food of any
kind; the influence of undrained lands; defective ventilation
and drainage of stables; to food and water contaminated with the morbid products of animals which have died of blood disease. In one remarkable outbreak which came immediately under my notice, the disease appeared amongst sucking calves of the pure shorthorn breed, and which had never partaken of other food than what they obtained by sucking, the dams remaining healthy. Anthrax is also disseminated through the agency of flies, and Bollinger, who has observed that the disease is often most prevalent when flies are in the greatest abundance, has induced it in rabbits by inoculating them with flies caught on the carcases of animals dead from anthrax. The flies, however, resist the influence of the virus, although bactericides are found in them.

PATHOLOGY.

The influence of all these causes upon the animal economy, differing widely in their primary stages, induce within the blood certain changes which ultimately tend to grave alterations in its composition, and to its death and decomposition.

First of all we must consider the influence of highly nutritious and nitrogenous fodder when suddenly brought to bear upon the animal body, and veterinarians are generally agreed that the result is the rapid formation of blood, highly charged with albuminous materials, which neither the tissue-nutrition nor the excretory organs are calculated to keep in anything like its normal condition. In consequence of this, grave changes occur, by which its constituents become degraded, and the system eventually empoisoned. If it be remembered that every tissue and organ in the body, by withdrawing from the blood those constituents which are essential to their well-being, serve as excretory organs to the rest of the body, the subject will be more clearly understood. Without this withdrawal from the blood of those constituents by every tissue and organ, it soon becomes unfit for the purposes for which it is intended, and the same condition results when it is so rapidly (and hence imperfectly) formed, that the process of tissue-nutrition cannot possibly eliminate or withdraw from it more than a moiety of its superabundant constituents.

For example, the whole of the body requires within a given time a certain quantity of plasma for all the purposes of
nutrition, growth, heat, the formation of fat, and what is eliminated by the excretory organs; and if within that period the quantity of that plasma far exceeds those requirements, it naturally follows that the unused matter must accumulate in the circulation, and there undergo such grave alterations as to become injurious to the animal economy, enpoison the blood, modify its power of absorbing and conveying oxygen from the lungs, destroy the integrity of the blood-corpuscles, and convert it into a proper habitat for the development and growth of low organisms, which cause within it a septic or putrefactive action, by which its vitality is ultimately destroyed; in fact bring about a condition of the blood similar to that which can be produced artificially by the introduction of decomposing animal matter, or by giving it with the food upon which the animal is fed. When blood is so altered, it tends to accumulate in the vessels of the soft structures of the body, such as the areolar tissue, spleen, enteric mucous membrane, and lungs, where it rapidly transudes through the walls of the altered and debilitated blood-vessels, and constitutes the various local manifestations of a septic fever.

In studying the course and progress of this malady, one cannot help being struck with its great similarity to the typhus fever of man. Both are induced by causes which alter the condition of the blood. Typhus is held to be highly contagious. Charbon is also contagious by inoculation. Neither in typhus nor charbon is there a constant or characteristic change in one particular organ, the morbid anatomy of typhus being summed up as follows:—A fluid condition of the blood; hyperæmia of the cerebral membranes and increase of intracranial fluid; bronchial catarrh and pulmonary hypostasis; softening of the heart, liver, spleen, and pancreas; hyperæmia and hypertrophy of the kidneys.

Further, it may be urged in support of this view that the eruptions of both diseases resemble each other in those cases where death is not almost instantaneous, viz., dark purple or crimson petechiae. There are also subcutis tendinum, or involuntary twitchings, both in typhus and in charbon. The red globules of the blood in both diseases show a marked deviation from their normal character, part with their colouring matter, and dissolve more rapidly than when in their natural condition. The
blood also contains an increased amount of ammonia, from de-
composition of the nitrogenous constituents, and finally both
diseases are apt to terminate in gangrene of the lungs. It is very
true that typhus is not so rapidly fatal as its analogue. This
is the case with almost every disease of the lower animals;
they are more rapidly fatal than similar diseases in man. Cases,
however, occur, where typhus kills during its primary stages by
syncope or coma, or generally from a combination of both.
When from syncope, the heart’s action is enfeebled from paralysis
or disease of its muscular tissue; and when from coma, the
blood has undergone such modifications as render it incapable
of supporting the changes essential to existence, its contamina-
tion being mainly due to the admixture of urea and other
products of the retrograde metamorphosis of tissue, and from
the diminution and destruction or solution of its red corpuscles
—changes similar to those seen in the blood of cattle which
have died of splenic apoplexy or black-quarter.

In opposition to the view of the spontaneous origin of
anthrax, we have the observations of many eminent pathologists,
who maintain that the malady is due to the propagation of a
new well-known organism, the Bacillus anthracis, the history of
which is as follows.

These organisms were first observed by Brauell, and afterwards
by Delafond and Gruby, in the blood of animals which had
died of anthrax, as peculiar staff-shaped bodies, which Delafond
designated bâtonnets, and which were believed to be products of
putrefaction, and that anthrax was a septicemia or putrefaction
of the blood. These bâtonnets were afterwards observed in
1850 by MM. Davaine and Rayer, and some time later Koch
studied them, and found the aqueous humor of the ox’s eye to
be particularly suitable for their nutrition. With a drop of the
aqueous humor he mixed the smallest
speck of a liquid containing the
rods, placed it under the microscope,
warmed it suitably, and watched the
subsequent action. During the first
two hours hardly any change was
noticeable, but at the end of that
period the rods began to lengthen, and the action was so rapid
that at the end of three or four hours they had attained from
twenty to thirty times their original length, and at the end of a few additional hours had formed filaments in many cases a hundred times the length of the original rods; and further it was seen that within the transparent rods little dots appeared; these became more and more distinct until the whole organism was studded with minute ovoid bodies like peas within their shell. After a time the integument fell to pieces, the place of each rod being taken by a long row of seeds or spores. Koch concluded that these spores, as distinguished from the rods, constituted the contagium of the disease in its most deadly and persistent form.

By inoculating animals with the fresh blood of an animal suffering from splenic fever, he found that they invariably died within twenty to thirty hours after inoculation. By drying the infectious blood containing the rod-like organisms, in which, however, the spores were not developed, he found the contagion to be fugitive, maintaining its power of infection for five weeks at the furthest. He then dried the blood containing the fully developed spores, and exposed it to a variety of conditions. He permitted the dried blood to assume the form of dust, wetted this dust, allowed it to dry again, placed it for an indefinite period in the midst of putrefying matter, and subjected it to other tests. After keeping this spore-charged blood, which had been treated in this fashion for four years, he inoculated a number of mice with it, and found its action as fatal as that of blood fresh drawn from the veins of an animal suffering from splenic fever, each spore in the millions contained in the diseased blood being sufficient to produce the disease.

The bacilli are not always found in the blood of living animals suffering from the disease; indeed, they generally appear a few hours before death, which never takes place in less than twenty hours, and then only singly and in very small
numbers. Even after death they cannot always be found in the blood, but always in the spleen. Their number, however, varies with the animal inoculated; in the guinea-pig they are numerous, sometimes exceeding the blood corpuscles; in the rabbit much smaller, and in the mouse often absent altogether. If the disease has been induced by inoculation, they are present, though in variable numbers, in the inoculation carbuncle. Though the rods are not always found in the blood, the spores are said to be invariably present, and some assert that it is their product that destroys life.

The bacilli rods, as found in the blood and spleen, vary in length very considerably, those in the spleen being longer; the shortest rods being in length generally about twice the diameter of a human red corpuscle, the longer ones two or three times the length of the shorter; but when carefully examined, the latter will be seen in a process of division into two or more segments. According to the observations of Koch, it appears that, whatever be the species of animal inoculated with anthrax blood, and no matter how many successive inoculations may be made, the bacilli multiply solely by fission, but only so long as the animal is alive; when dead a minute portion of its blood, placed in aqueous humor, and kept at a temperature of 35° to 37° C. (95° F.), the rods, as already stated, lengthen out very considerably. This process of lengthening of the rods into filaments is apparently effected by the temperature. In five hours a rod at a temperature of 32° C. (89·36° F.) may have increased so as to be from eighty to one hundred times its original length, and in twenty-four hours the filament may be full of spores. If the temperature, however, be kept about 26° C. (82·24° F.), the spores may not appear till the thirty-sixth or fortyieth hour. When the spores have once appeared, all the other changes go on at ordinary temperatures from 12° (53·36° F.) to 18° C. (64·24° F.), but not nearly so rapidly, even when the preparation is kept in the sun for a few hours daily, as when artificial heat is applied. On the other hand, a high temperature, 37° to 40° C. (98·36° to 104° F.), at once checks all developmental changes.

The filaments differ in cultivated specimens very much in their arrangements. Sometimes they form a network—indeed a mycelium—made up of numerous, nearly parallel, unbranched
threads, crossing each other at different levels; the threads are sometimes straight, but have generally a wavy outline. This condition may obtain throughout the whole preparation, but generally at some parts the filaments are extremely irregular and much convoluted.

It has been stated by several observers (Koch, Bollinger, Siedamgrotzky, &c.) that the bacilli are always motionless; but if Dr. Cossar Ewart's observations are correct, this condition is not constant.

Pasteur stated that the spores of bacilli remained toxic after boiling; and after being subjected to a pressure of twelve atmospheres of oxygen, Dr. Burdon Sanderson and Dr. Cossar Ewart tested the accuracy of this statement, and found that mice inoculated with the boiled and compressed solutions remained quite well.

The experiments of Bert, however, support to some extent the conclusions of Pasteur. In a series of experiments Bert submitted anthrax blood to the action of considerably compressed oxygen, and found the bacilli had disappeared, killed by the oxygen, and yet the blood retained its virulence, for it killed rabbits, guinea-pigs, and dogs inoculated with it; and in another series of experiments Bert took anthrax blood containing bacilli, and added drop by drop of absolute alcohol to it, until a precipitate was formed, and which was dried in vacuum. This dried powder was injected under the skin, and it killed a rabbit, a guinea-pig, and even a dog.

If this alcoholized precipitate be dissolved in water and filtered, the filtrate is still virulent. If alcohol is again added to it, it forms a flocculent matter, which is deposited at the bottom of the vessel. Collected on a filter and dried, this precipitate is still toxic. It would therefore appear that the active or virulent element of anthrax resists absolute alcohol, and that it resists oxygen, and that it is precipitated by alcohol and soluble in water. It behaves itself something like diastase, except that, whatever may be its nature, it can reproduce itself to an indefinite extent; while it is asserted by some authorities that diastase cannot reproduce itself.

Putting aside the conclusions of Colin—that the bacilli are simple transformation of the blood-corpuscles—we are left between two sets of conclusions. Those of Koch and others
point to splenic fever being due to a minute organism possessing wonderful powers of resistance and reproduction; Bert's to something independent of the presence or absence of animal or vegetable organisms, and which resists the action of compressed oxygen and absolute alcohol, which would, he asserts, kill everything possessing life: this something he is of opinion is a substance analogous to diastase.

Blood containing bacilli, if dried in very thin layers, by being exposed to the air in a shady place, was found by Koch to lose its virulence and its power of developing elongated fibres after twelve to thirty hours. Thicker layers retained their powers for two or three weeks; and some still thicker for four or five weeks. After a longer time they were never capable of producing the disease.

Koch also found that if the bacilli were deprived of air they soon died.

When rubbed up with the blood or aqueous or vitreous humor of an ox, and placed in a well-closed glass vessel, there quickly ensued an odour of putrefaction; the bacilli disappeared after twenty-four hours without the fibres enlarging, and lost their infective power. That their death was due to the absence of oxygen was shown by placing a drop of blood infected by the bacilli under the microscope. Examined by the micro-spectroscope it gave the bands of oxy-haemoglobin; the fibres in this drop increased four or five times in length in three hours, but after that time the oxygen was clearly used up, as the presence of the absorption band of reduced haemoglobin proved. From this moment the growth of the bacillary fibres ceased, although true putrefaction had not set in.

When the spores and bacilli are separated from the blood by filtration, the blood is said to be rendered innocuous; and when pregnant animals become affected, or have been inoculated, the blood of the fetus does not become diseased, and other creatures can be inoculated with it and suffer no harm, the intervening membranes acting the part of a filter. The bacilli also disappear in liquids in the presence of carbonic acid, and the blood soon loses its specific property.

This proves that, to live and grow, the bacilli require to absorb oxygen and give out carbonic acid; hence they are what M. Pasteur terms "aerobic." If the fluid which contains them
begins to putrefy they are destroyed, not only by being deprived of oxygen, but by being brought into contact with other organisms, such as the vibrios of putrefaction, in the presence of which, and of all other low forms of organisms, they either do not develop at all, or develop with great difficulty. The vibrios of putrefaction are not aërobic, and cease to move when brought in contact with oxygen; disappear, being transformed into refracting corpuscles, which in a suitable soil reproduce motile vibrios, and multiply with extreme rapidity in a putrefying fluid. If an animal be inoculated with it when in this condition, it does not die of anthrax, but of septicemia, the symptoms of which, when produced in guinea-pigs with the blood of a horse which had been dead of charbon twenty-four hours, and which contained vibrios of putrefaction as well as some bacilli, and with the blood of a cow which had been dead forty-eight hours, and which contained a preponderating quantity of vibrios, were violent inflammation of all the muscles of the abdomen and limbs, and here and there, especially on the ears, bullae formed containing gas. The blood was diffusent, and on examining these animals immediately after death, M. Pasteur found that the muscles were filled with active vibrios of putrefaction, and in the peritoneal cavity they had undergone extraordinary development; one drop of this serosity taken from an animal still living, affected another animal profoundly, while a drop of blood from the heart had no effect.

Again, dilution of the fluid containing the bacilli with a moderate amount of water has no effect on its virulence, but a large quantity destroys it, and traces of carbolic acid prevent the development of the bacilli.

It has been stated that the bacilli destroy life—(1.) By acting as asphyxiants, depriving the blood of its oxygen; and (2.) By mechanically obstructing the blood-vessels. Against both these theories must be placed the fact that they are very few in number, indeed often absent altogether in the blood during life.

Anthrax is not transmitted by infection from one animal to another, for animals kept in the closest proximity to diseased ones, and placed under the most favourable conditions for infection through the air, do not become diseased.

Mice and rabbits seem capable of eating food containing bacilli with impunity, and flies can gorge themselves with the
infected blood and suffer no harm; but horses, cattle, pigs, dogs, cats, and ferrets succumb after partaking of food and water contaminated with the virus.

The local effects of inoculation of the skin with anthrax blood is as follows:—In twenty-four hours there is redness of the spot, with heat, swelling of the skin and subcutaneous tissue, extending from a third of an inch to an inch in depth.

The swelling increases in forty-eight hours to perhaps two inches, and on the third day, if the animal survive, to several inches; the heat and redness being most intense at the inoculated spot. The process extends in the connective tissue, particularly along the track of the lymphatics. In superficial inoculations bacilli can be seen in every instance in twenty-four hours, at a distance only of about one-fourth of an inch, but their after extension is not proportionate to the extent of the tumefaction, nor does the serum found in the swelling contain many of them until after forty-eight hours, when great quantities will be found in it; when the virus is injected into the subcutaneous tissue death may occur without bacilli being found at the point of injection.

The production of the disease by inoculation, particularly with cultivated spores, is a strong proof in its favour; but, on the other hand, there exists the fact that the disease is often produced by over-feeding, even on food of good quality, unless indeed it can be proved that the spores or bacilli are contained in the food or atmosphere; but at the same time it must not be forgotten that the bacilli are seemingly not present until the disease has made considerable progress, until in fact the animal is at the point of death, when its temperature is considerably diminished; that (according to Dr. Cossar Ewart) the development of the bacilli is at once checked by a temperature of from 37° to 40° C. (98.6° to 104° F., the natural temperature of the ox being about 102° F.); and judging by the results of the experiments of Bert, and having knowledge of a remarkable outbreak amongst calves which had never tasted any food but what milk they sucked, the dams being healthy, one is forced to the conclusion that the disease is due to a virus which renders the blood a fit habitat for this peculiar organism, between the spores of which and the virus there seems to be an almost indestructible affinity.
The process by which a virus is developed may be analogous to what takes place in the conversion of grape sugar into alcohol and carbonic acid.

Here we have, first of all, a solution of an organic compound—sugar—\( C_6H_{12}O_6 \); and, second, a vegetable organism—the yeast plant—which, when added to the solution of sugar, reproduces itself, grows, develops new generations, and during this generative or reproductive process alters the constitution of the saccharine solution, converting it into alcohol, \( C_2H_6O \), and carbonic acid, \( CO_2 \).

The same may be said of the action of microbes on animal fluids—that by reproducing themselves they change the nature of the blood, converting it into a material unfit to maintain life.

**INOCULATION FOR THE PREVENTION OF ANTHRAX AND FOWL CHOLERA.**

Few investigations, marking as they do an epoch in pathological science, have had more immediate and practical results than those of Pasteur, Toussaint, Chauveau, Koch, Klebs, on anthrax; of Arloing, Cornevin, and Thomas, on symptomatic anthrax, or Chabert's disease, and amongst others those of Mr. R. Rutherford, of Edinburgh, on pleuro-pneumonia contagiosa. The experiments of Pasteur, now very widely known, are to some extent the outcome of the experiments of Dr. Burdon Sanderson, Mr. Duguid, and afterwards of Dr. Greenfield, conducted at the Brown Institution, London. In 1878 it was discovered by Dr. Burdon Sanderson and Mr. Duguid that cattle might be inoculated with splenic fever from a guinea-pig, and though such inoculation caused the development of serious symptoms, the animals did not die; and in continuing these experiments it was found that cattle once so inoculated resisted the results of further inoculation—that in fact they could be thus rendered insusceptible to future attacks of splenic fever. Dr. Greenfield, in making a series of experiments with the view of obtaining a suitable virus for inoculation, found that the virus modified by transmission through the guinea-pig, and cultivated under particular conditions, gradually lost its activity, and at
last became practically inert; and it occurred to him that, by making use of this fact, a virus might be obtained so far modified as to be sufficient to ensure protection and yet not endanger the life of an animal inoculated with it, and this he found could be done with success.

The priority of this discovery is therefore claimed for England, but the merit of working out its details is undoubtedly due to Pasteur.

Toussaint of Toulouse had discovered that the so-called "Fowl Cholera" was due to an organism which he supposed to be similar to the yeast plant; and in a series of experiments with this organism Pasteur arrived at some startling conclusions, which were explained by him in his address delivered at the International Medical Congress in 1881. He spoke as follows:

"The subject of my communication is vaccination in relation to chicken cholera and splenic fever, and a statement of the method by which we have arrived at these results—a method the fruitfulness of which inspires me with boundless anticipations. Before discussing the question of splenic fever vaccine, which is the most important, permit me to recall the results of my investigations of chicken cholera. It is through this inquiry that new and highly important principles have been introduced into science concerning the virus or contagious quality of transmissible diseases. More than once in what I am about to say I shall employ the expression virus-culture, as formerly, in my investigations on fermentation, I used the expressions, the culture of milk ferment, the culture of the butyric vibion, &c. Let us take, then, a fowl which is about to die of chicken cholera, and let us dip the end of a delicate glass rod in the blood of the fowl with the usual precautions, upon which I need not here dwell. Let us then touch with this charged point some bouillon de poule, very clear, but first of all rendered sterile under a temperature of about 115° Centigrade, and under conditions in which neither the outer air nor the vases employed can introduce exterior germs—those germs which are in the air, or on the surface of all objects. In a short time, if the little culture vases is placed in a temperature of 25° to 35°, you will see the liquid become turbid, and full of tiny microbes, shaped like the figure 8, but often so small that under a high magnifying power they appear like points. Take from this vase a drop as small as you please, no more than can be carried on the point of a glass rod as sharp as a needle, and touch with this point a fresh quantity of sterilised bouillon de poule placed in a second vase, and the same phenomenon is produced. You deal
in the same way with a third culture vase, with a fourth, and so on to a hundred, or even a thousand, and invariably within a few hours the culture liquid becomes turbid and filled with the same minute organisms. At the end of two or three days' exposure to a temperature of about 30° C. the thickness of the liquid disappears, and a sediment is formed at the bottom of the vase. This signifies that the development of the minute organism has ceased—in other words, all the little points which caused the turbid appearance of the liquid have fallen to the bottom of the vase, and things will remain in this condition for a longer or shorter time, for months even, without either the liquid or the deposit undergoing any visible modification, inasmuch as we have taken care to exclude the germs of the atmosphere. A little stopper of cotton sifts the air which enters or issues from the vase through changes of temperature. Let us take one of our series of culture preparations—the hundredth or the thousandth, for instance—and compare it in respect to its virulence with the blood of a fowl which has died of cholera; in other words, let us inoculate under the skin ten fowls, for instance, each separately with a tiny drop of infectious blood, and ten others with a similar quantity of the liquid in which the deposit has first been shaken up. Strange to say, the latter ten fowls will die as quickly and with the same symptoms as the former ten; the blood of all will be found to contain after death the same minute infectious organisms. This equality, so to speak, in the virulence both of the culture preparation and of the blood, is due to an apparently futile circumstance. I have made a hundred culture preparations—at least I have understood that this was done—without leaving any considerable interval between the impregnations. Well, here we have the cause of the equality in the virulence. Let us now repeat exactly our successive cultures with this single difference, that we pass from one culture to that which follows it—from the hundredth to, say, the hundred and first—at intervals of a fortnight, a month, two months, three months, or ten months. If, now, we compare the virulence of the successive cultures, a great change will be observed. It will be readily seen from an inoculation of a series of ten fowls that the virulence of one culture differs from that of the blood and from that of a preceding culture when a sufficiently long interval elapses between the impregnation of one culture with the microbe of the preceding. More than that, we may recognize by this mode of observation that it is possible to prepare cultures of varying degrees of virulence. One preparation will kill eight fowls out of ten, another five out of ten, another one out of ten, another none at all, although the microbe may still be cultivated. In fact, what is no less strange, if you take each of these cultures of attenuated virulence as a point of departure in the
preparation of successive cultures and without appreciable interval in the impregnation, the whole series of these cultures will reproduce the attenuated virulence of that which has served as the starting-point. Similarly, where the virulence is null it produces no effect. How, then, it may be asked, are the effects of these attenuating virulences revealed in the fowls? They are revealed by a local disorder, by a morbid modification more or less profound in a muscle, if it is a muscle which has been inoculated with the virus. The muscle is filled with microbes which are easily recognised, because the attenuated microbes have almost the bulk, the form, and the appearance of the most virulent microbes. But why is not the local disorder followed by death? For the moment let us answer by a statement of facts. They are these: the local disorder ceases of itself more or less speedily, the microbe is absorbed and digested, if one may say so, and little by little the muscle regains its normal condition. Then the disease has disappeared. When we inoculate with the microbe the virulence of which is null, there is not even local disorder, the *natura medica tirius* carries it off at once, and here, indeed, we see the influence of the resistance of life, since this microbe, the virulence of which is null, multiplies itself. A little further, and we touch the principle of vaccination. When the fowls have been rendered sufficiently ill by the attenuated virus which the vital resistance has arrested in its development, they will, when inoculated with virulent virus, suffer no evil effects, or only effects of a passing character. In fact, they no longer die from the mortal virus, and for a time sufficiently long, which in some cases may exceed a year, chicken cholera cannot touch them, especially under the ordinary condition of contagion which exists in fowl-houses. At this critical point of our manipulation—that is to say, in this interval of time which we have placed between two cultures, and which causes the attenuation—what occurs? I shall show you that in this interval the agent which intervenes is the oxygen of the air. Nothing more easily admits of proof. Let us produce a culture in a tube containing very little air, and close this tube with an enameller’s lamp. The microbe in developing itself will speedily take all the oxygen of the tube and of the liquid, after which it will be quite free from contact with oxygen. In this case it does not appear that the microbe becomes appreciably attenuated, even after a great lapse of time. The oxygen of the air, then, would seem to be a possible modifying agent of the virulence of the microbe of chicken cholera—that is to say, it may modify more or less the facility of its development in the body of animals. May we not be here in presence of a general law applicable to all kinds of virus? What benefits may not be the result? We may hope to discover in
this way the vaccine of all virulent diseases; and what is more natural
than to begin our investigation of the vaccine of what we in France
call charbon, what you in England call splenic fever, and what in
Russia is known as the Siberian pest, and in Germany as the Milzbrand.
In this new investigation I have had the assistance of two devoted
young savants—MM. Chamberland and Roux. At the outset we
were met by a difficulty. Among the inferior organisms, all do not
resolve themselves into those corpuscle germs which I was the first
to point out as one of the forms of their possible development. Many
infectious microbes do not resolve themselves in their cultures into
corpuscle germs. Such is equally the case with beer yeast, which we
do not see develop itself usually in breweries, for instance, except by
a sort of scissiparity. One cell makes two or more, which form them-
selves in wreaths; the cells become detached, and the process recom-
menes. In these cells real germs are not usually seen. The microbe
of chicken cholera and many others behave in this way, so much so
that the cultures of this microbe, although they may last for months
without losing their power of fresh cultivation, perish finally like beer
yeast which has exhausted all its aliments. The anthracoid microbe
in artificial cultures behaves very differently. In the blood of animals,
as in cultures, it is found in translucent filaments more or less seg-
mented. This blood or these cultures freely exposed to air, instead
of continuing according to the first mode of generation, show at the
end of forty-eight hours corpuscle germs distributed in series more or
less regular along the filaments. All around these corpuscles matter
is absorbed, as I have represented it formerly in one of the plates of
my work on the diseases of silkworms. Little by little all connection
between them disappears, and presently they are reduced to nothing
more than germ dust. If you make these corpuscles germinate, the
new culture reproduces the virulence peculiar to the thready form
which has produced these corpuscles, and this result is seen even after
a long exposure of these germs to contact with air. Recently we
discovered them in pits in which animals dead of splenic fever had been
buried for twelve years, and their culture was as virulent as that from
the blood of an animal recently dead. Here I regret extremely to be
obliged to shorten my remarks. I should have had much pleasure
in demonstrating that the anthracoid germs in the earth of pits in
which animals have been buried are brought to the surface by
earthworms, and that in this fact we may find the whole etiology of
disease, inasmuch as the animals swallow these germs with their
food. A great difficulty presents itself when we attempt to apply
our method of attenuation by the oxygen of the air to the anthra-
coid microbes. The virulence establishing itself very quickly, often
after four-and-twenty hours in an anthracoid germ which escapes the action of the air, it was impossible to think of discovering the vaccine of splenic fever in the conditions which had yielded that of chicken cholera. But was there, after all, reason to be discouraged? Certainly not; in fact, if you observe closely, you will find that there is no real difference between the mode of the generation of the anthracoid germ by scission and that of chicken cholera. We had therefore reason to hope that we might overcome the difficulty which stopped us by endeavouring to prevent the anthracoid microbe from producing corpuscle germs, and to keep it in this condition in contact with oxygen for days, and weeks, and months. The experiment fortunately succeeded. In the ineffective (neutre) bouillon de poule the anthracoid microbe is no longer cultivable at 45° C. Its culture, however, is easy at 42° or 43°, but in these conditions the microbe yields no spores. Consequently it is possible to maintain in contact with the pure air at 42° or 43° a mycélienne culture of bacteria entirely free of germs. Then appear the very remarkable results which follow.

In a month or six weeks the culture dies—that is to say, if one impregnates fresh bouillon with it, the latter is completely sterile. Up till that time life exists in the vases exposed to air and heat. If we examine the virulence of the culture at the end of two days, four days, six days, eight days, &c., it will be found that long before the death of the culture the microbe has lost all virulence, although still cultivable. Before this period it is found that the culture presents a series of attenuated virulences. Everything is similar to what happens in respect to the microbe in chicken cholera. Besides, each of these conditions of attenuated virulence may be reproduced by culture; in fact, since the charbon does not operate a second time (ne récidive pas), each of our attenuated anthracoid microbes constitutes for the superior microbe a vaccine—that is to say, a virus capable of producing a milder disease. Here, then, we have a method of preparing the vaccine of splenic fever. You will see presently the practical importance of this result, but what interests us more particularly is to observe that we have here a proof that we are in possession of a general method of preparing virus vaccine based upon the action of the oxygen and the air—that is to say, of a cosmic force existing everywhere on the surface of the globe. I regret to be unable from want of time to show you that all these attenuated forms of virus may very easily, by a physiological artifice, be made to recover their original maximum virulence. The method I have just explained of obtaining the vaccine of splenic fever was no sooner made known than it was very extensively employed to prevent the splenic affection. In France we lose every year by splenic fever animals of the value of 20,000,000£. I was asked to give a public demonstration of the results already mem-
tioned. This experiment I may relate in a few words. Fifty sheep were placed at my disposition, of which twenty-five were vaccinated. A fortnight afterwards the fifty sheep were inoculated with the most virulent anthracoid microbes. The twenty-five vaccinated sheep resisted the infection; the twenty-five unvaccinated died of splenic fever within fifty hours. Since that time my energies have been taxed to meet the demands of farmers for supplies of this vaccine. In the space of fifteen days we have vaccinated in the departments surrounding Paris more than 20,000 sheep, and a large number of cattle and horses. If I were not pressed for time I should bring to your notice two other kinds of virus attenuated by similar means. These experiments will be communicated by-and-by to the public. I cannot conclude, gentlemen, without expressing the great pleasure I feel at the thought that it is as a member of an International Medical Congress assembled in England that I make known the most recent results of vaccination upon a disease more terrible, perhaps, for domestic animals than small-pox is for man. I have given to vaccination an extension which science, I hope, will accept as a homage paid to the merit and to the immense services rendered by one of the greatest men of England.—Jenner. What a pleasure for me to do honour to this immortal name in this noble and hospitable city of London!"

**VARIETIES OF ANTHRAX.**

The more recent investigators are disposed to confine the term anthrax to that form of disease characterised by black tumour, associated with the presence in the economy of the *Bacillus anthracis*; but as the term merely indicates a symptom—namely, a black tumour, the charbon (coal-like) of the French—I intend to include under it all those diseases in which it is an expression or a symptom, contenting myself by pointing out in which of them the bacilli have been discovered, and which are proved to be contagious.

Chabert designates anthrax or charbonous diseases as foul affections of different natures, and external tumours terminating in mortification of the tissues, and divides them into three kinds, namely:—

1st. *Charbonous or Anthrax Fever.*—In this form there are no external manifestations, and it is rapidly fatal; the *post mortem* appearances being engorgement and congestion of the spleen, liver, mesentery, intestinal mucous membrane, the sublumbar
tissues, lungs, and heart. In some cases death is preceded by roughness of the coat, dry, hot skin, excessive sensibility over the dorsal lumbar region, choking cough, glairy discharge from the nostrils, and a quick, strong pulse. Sometimes the animal may live long enough for level tumours to form under the skin; but very often the patients succumb, without presenting the least symptom of the malady, in a few hours after the first appearance of illness. One remarkable instance of the rapidity of death from anthrax occurred in the practice of the author on the 26th March 1879. The animal was a carriage horse, which had been driven from Liberton to Edinburgh, being in apparently perfect health when it left home, and did its work up to the very moment of its death, which occurred on the street, just as the owner's wife was stepping into the carriage at a shop door. The carcass was sent to the college for an opinion as to the cause of death. Upon dissection it was discovered that the right auricle was ruptured in two places, both it and the walls of the ventricle being chronically atrophied and attenuated. A large black tumour was found in the lungs, and the pulmonary arteries were engorged with black tarry blood, which, when microscopically examined, was found to contain the bacilli in a most perfect form, and very numerous indeed; Dr. Hamilton, pathologist to the Royal Infirmary, and Dr. Cossar Ewart, to whom the blood was submitted for examination, stating they were as perfect as any specimens they had ever seen.

Doubtless the death of this animal was immediately due to the rupture of the auricular walls, but the condition (fulness) of the vessels and the lungs made it apparent that the animal could not have lived many minutes, even if the heart had not given way.

2d. Symptomatic Charbon, in which there is a general morbid state succeeded by external tumours.

3d. Essential Charbon, or that form of external tumour unpreceded by fever and resulting from inoculation; the malignant pustule of Dr. W. Budd—a form rarely met with in the lower animal.

ANTHRAX IN THE HORSE.

Anthrax in the horse rarely occurs in this country, but is prevalent in India, where it is said to attack the elephant as
well as other animals, and is there termed "Loddiana Disease," and in Africa the "Horse Sickness."

Symptoms.—I. Without external eruption.

The animal may appear dull, walking with a heavy, feeble step, then fall prostrate in a state of somnolence; if it be standing, the head hangs down, resting on the manger or other solid body. It sometimes stands back in the stall, resting the body on the side, and finally becomes restive, stamps with the feet, looks to the sides and flanks, and shows other signs of colic.

If the disease comes on whilst the animal is at work, added to the above symptoms there is extreme lassitude, great weakness of the lumbar muscles and posterior extremities, with staggering gait. The skin has lost its suppleness, is hot, and slightly crepitates on the back, over the kidneys, and sides; the coat is rough and bristly in some parts; and there are partial or general tremblings of the muscles, and flow of saliva from the mouth. There are sweats, alternating from hot to cold. At the base of the ears, and behind the elbows, the veins become augmented in volume. Above all, the lymphatic ganglia of the groin are swollen; and if the horse be entire, the testicles move rapidly up and down. Great excitement now sets in, the animal is irritable and timorous, and afterwards becomes unconscious of all around. The conjunctivae are yellow or reddish-yellow; and sometimes petechial spots are present on the visible mucous membranes.

The pulse is small and thready; the beatings of the heart are, however, strong, and are accompanied by a metallic tinkle. The respiration is often irregular, and often associated with roaring.

These symptoms may insensibly disappear, or may be succeeded by a critical eruption. At other times, even after the animal has seemed to rally, aggravation of the symptoms takes place. The animal grinds its teeth, has violent colic, rolls about, carrying its head to its flanks; the muscles of the head and neck are agitated by convulsive movements; the eyes are haggard and wandering; the mucous membrane injected, and of a brown or red tinge; the heart beats with extreme violence, very irregularly, and accompanied by a strong metallic sound; the pulse is trembling or double, and very small; the respirations tumultuous and agitated; the nostrils dilated, and clots of yellow serosity and blood escape by the nose; the mouth
is filled with a mucous foam, the tongue is tumefied, and of a deep bluish-red colour; tears, sometimes tinged with blood, flow from the sunken and haggard eyes. The belly is sensitive when pressed upon, tympanitic, and the excremental matters are often liquid and mixed with blood clots; the rectum is often everted, appearing as a tumour, folded and livid; the temperature of the skin is lowered; the countenance is particularly anxious, the face shrunked. The muscular force now becomes exhausted; the animal falls to the ground; convulsions come on, more particularly of the neck and extremities; and finally it succumbs, after a few moments of calmness, which, succeeding a paroxysm, always precedes death. The disease may terminate in from six to forty-eight hours after the manifestation of the first symptoms. The ordinary time is from twelve to twenty-four hours, unless external eruption eliminates the morbid material from the body.

In the spring of this year, 1894, a remarkable outbreak of charbonous fever, presenting the salient symptoms of Loodiana disease, occurred in a large stud of cart-horses under the care of Messrs. Leather, veterinary surgeons, Liverpool, and which had been, for some time previously, fed on an Indian pea (Pisum sativum), called in Liverpool Indian mutters. Mutur is the Hindustani word for the common pea (Pisum sativum), but that brought to Liverpool is different from the ordinary pea of this country, and resembles a lentil more than a pea. It is imported into Glasgow from India in large quantities, I believe, mostly as ballast, and has, I am told, not only been given to horses, but ground and mixed with various cakes for cattle, and with many fatal consequences.

However, in the outbreak at Liverpool, it appears that horses commenced to die very suddenly some time after the owners had commenced to use the mutters, and for several weeks after they had discontinued to use them they still died. The symptoms were roaring, hemorrhage from the nose, great prostration, swelling of the throat, succeeded in many cases by sudden death. Other horses, however, lived a considerable period; but none recovered in which roaring had become pronounced.

I saw them in March, and found two dead on my arrival—one having only been dead a few hours; and from the blood of which I obtained the bacilli shown in the drawing.
On examining the food everything was found to be of the best and cleanest quality; but the Indian mutters were very dirty, dusty, and mixed with the excrement of rats; and from this dust bacilli identical with those found in the blood were cultivated; but in no instance did I succeed in obtaining bacilli from the interior of the grain. From this it may be inferred that the microbes were in the dirt surrounding the grain, but not in the mutters themselves, and that by proper washing and cleaning they might be a safe diet.

This, however, requires further investigation, as animals have died on the Continent presenting similar symptoms to those at Liverpool after being fed on the legumen "Lathyrus sativus," a bitter legumen, but whether from a vegetable poison contained in the legumen or from bacillary growths has not yet been determined.

Leguminous plants are often provided with small tuberous roots, and in these roots there occur almost invariably, and in great numbers, peculiar rod-like structures which have been identified as bacteria. Woronin, for example, in 1866, examined the root tubers of Lupinus mutabilis, and found the rod-like bacteria present in considerable numbers. Eriksson investigated the matter further in 1874, and found in the tubers long tubular
structures, which he considered to be the hyphæ of a fungus; and he described the bacteria described by Woronin as nothing but detached parts of the hyphæ.

The tubers themselves in which these hyphæ and bacteria occur have been considered by some as diseased outgrowths caused by the pressure of the fungi, but others have regarded them as peculiar modifications of adventitious roots, in which the fungi have taken up their abode. Water culture experiments have been made to determine whether these tuberous growths are caused by the fungus or not, and it was found that plants (red clover being selected) growing in solutions rich in nitrogenous substances developed little or none of the tuberous growths, whereas those growing in solutions containing the least amount of nitrogenous matters developed numerous tubers. Whether these tubers were developed or not, the bacteria were still present. Whether we look upon the tubers as normal outgrowths or pathological phenomena, we are forced to the conclusion, from the history, invasion, and progress of the disease in animals, that the bacteria, whether existent in the plants, or merely contained, as we suppose, in the dust, have some connection with the disease. This, however, as well as the disease induced by eating lupin, prevailing on the Continent, is well worthy of further consideration.

II. With external eruptions.—In the course of charbonous fever, often at its commencement, the first observable signs are tumours on the surface of the body. These tumours serve as a base to all the divisions and subdivisions of charbon, following their form, volume, situation; the degree of virulence of the accompanying fever; the resistance which they oppose to therapeutics; and finally, the physically morbid character which they present. They are thus divided into glosso-anthrax; avant cœur (in front of heart); cuisse noire, black leg; essential and symptomatic; benign and malign; charbon adhérante, phlegmonex; charbon blane (white charbon); charbon noir (black charbon).

Seat and anatomical character of the tumours—boutons (buboes).—They are developed principally in the subcutaneous areolar tissue, in those parts of the body where it is loose and abundant, as well as in the lymphatic glands and muscular tissue.

The development of these tumours is signalized by heat of the skin, standing out of the hairs, and often by slight crepitation in the areolar tissue when the skin is thick. At the beginning
they feel as nodosities placed in the areolar tissue. Each nodosity is about the size of a walnut, simple or compound in structure, round or irregular in form, and adhering to a pedicle at its base. They are painful, and the sensibility of the surrounding tissue is increased. When touched by the hand, a local shivering like a subcutaneous beating is felt; this character is special to charbon.

The phenomenon of crepitation arises from the affected tissue evolving gas; this constitutes crepitant and emphysematous charbon, and when emphysema occurs the tissues lose their sensibility, for on plunging a lancet into them the animal does not evince any pain. The liberated gas is fetid, and a brownish or black fluid escapes through the lancet puncture. This fluid corrodes and depletes the skin.

*Engorged tumours.*—These tumours are uniform; the skin by which they are covered is tense, cold to the touch; crepitant, and emphysematous; they exist on the back, sides, and quarters, and may extend and embrace the walls of the abdomen, sheath, or mammary gland, perineum, vulva or penis, anus; but they generally affect the head, and extend downwards, even to the chest, and as they increase the animal may bleed from the nose, show signs of suffocation, and if not speedily relieved death ensues in a very short time. The swelling of the head is a prominent symptom of the disease as seen in India.

*Glosso-Anthrax.*—On the surfaces of the mucous membranes, as the tongue, or inside of the lips, when tumours exist, phlyctene are sometimes seen, varying in size from that of a nut to a hen’s egg, constituting a softened mass filled with a sero-albuminious liquid of a brown or yellow colour, corrosive and acrid, destroying the tissue which surrounds it, and causing the formation of ulcers.

These phlyctenes ordinarily form some hours before death; they are simple or multiple, of a yellow-grey colour, resting on the surface of the mucous membrane; and their formation coincides with tumefaction of the surrounding tissues. The tongue then swells and hangs out of the mouth, becomes of a bluish or mulberry colour, and when the vesicles on its surface are broken by its movements, ulcers form with a red centre and a black circumference, discharging ichorous liquid mixed with saliva and blood. The swelling may extend to the base of the tongue, to the parotid region, and the animal may die of suffocation.
In animals which have white skins, or in which the eruption takes place in parts of the body void of hair or wool, red, brown, violet, or mulberry spots of bloody effusion are seen. These spots are independent of the tumours and extravasations, and sometimes exist on the surface of the tumours. They are most commonly seen in the pig and sheep.

Ecchymoses are seen on the visible mucous membranes. When the fever progresses slowly these spots unite by confluence, and surround, notably in the pig and sheep, the whole body. Some of them become crepitous and emphysematous; others take the form of tumours, passing rapidly to the state of gangrene. In addition to these eruptions, there is often a soreness and swelling of the throat, infiltration at the upper end of the trachea, and a discharge of a lymph-like material from the nostrils.

Charbonous tumours are generally of a black-brown colour. The phlyctæae are filled with a brown liquid, which is very irritating; it seeps on the surface as drops of cold serosity. The tumours have little tendency to suppuration, and speedily become gangrenous. If these symptoms are added to those furnished by the mucous membranes, no difficulty need be felt in diagnosing charbonous tumours, phlegmonous and gangrenous.

Terminations.—When the tumours resist mortification, they terminate by delitescence, by suppuration, and by metastasis.

1st. Delitescence.—The morbid products are effused, and constitute tumours, which are reabsorbed and expelled by the excretory organs. Examples of this kind of termination have been observed by veterinarians in Africa.

2d. Suppuration.—When the tumours progress in a slow manner, indurating gradually, suppuration may be brought about by therapeutic and surgical means. Resolution is slowly induced, and it is not without pain that the necessary suppuration can be provoked. The animals remain poor and unthriftly, and often in the horse glanders and farcy conclude this morbid state.

3d. Metastasis.—The amelioration of the symptoms which succeed the development of tumours is not often lasting. The products are reabsorbed and carried anew into the circulation. This unhappy crisis is announced by the reappearance of all the symptoms proper to charbonous fever; their succession is so rapid that death may take place in from eight to ten hours.
SYMPTOMS OF ANTHRAX FEVER IN HORNED CATTLE, APOPLEXY

Anthrax, splenic apoplexy, splenic fever.

The symptoms in the ox are very analogous to those in the horse. The ox suddenly goes off its feed; rumination is suspended; there are rigors and tremblings; partial sweats bedew the body, which is alternately hot and cold. The dorso-lumbar region is excessively tender to pressure, and when it is the seat of the tumour, very acute pain is thus caused; the gait becomes staggering, and the animal rapidly exhausted. A recumbent posture is almost constantly maintained; the animal will now and then attempt to rise, but will rarely succeed in doing so. When standing, the back is arched, the legs stiff and rigid, but the standing posture is not long maintained. The animal looks towards its flank, falls into convulsions, and expels, without much effort, soft and bloody matter by the anus. The heart beats with violence against the thoracic walls; the pulse is small, rapid, irregular, intermittent, and sometimes double; the conjunctiva red, injected, and reflect a blackish-red tint; the respiration is panting and plaintive; there is tympanitis of the abdomen; the tongue is bluish-red, and the mouth filled with mucus; blood escapes from the nose; the eyes are sunk in their orbits, and tears flow over the cheeks. The areolar tissue of the back and sides becomes crepitous to the touch, and the animal dies during a convulsive exacerbation, or during the succeeding calmness. In some animals the excitement is so great that it is dangerous to go near them. The rapidity with which the symptoms succeed each other is variable, death taking place in the space of from a few minutes to twenty hours.

In cattle above two years old, particularly milch cows, the local lesions are often confined to great congestion of the spleen, and to a lesser extent of the liver and mucous membrane of the intestinal canal. In other, but rarer instances, the engorgement may be in the lungs, and should the animal survive for some days, decomposition of the extravasated blood is established, as expressed by fetor of the breath; the decomposed extravasated blood being absorbed into the circulation, causing death by septicemia. I have also seen this condition in a sucking calf.

In true splenic apoplexy the spleen is often much enlarged, broken down in structure, and its capsule distended with a mass
of tar-like blood. If one end of the organ be elevated, it will be seen that the blood will gravitate into the most dependent part, showing that the splenic tissue is disintegrated, and that the blood is more or less fluid.

Death from splenic fever is very sudden; in many instances an animal seen a few hours before apparently in good health is found dead, death having apparently occurred without a struggle. If, however, the disease is not so rapid in its course, it may be noticed that there are various alterations in the symptoms; in some instances an animal will be unwell for several days, suffering from a remittent fever; one day very ill, with rapid, feeble pulse, hurried and painful breathing, red and injected eyes, hot mouth, irregularity of the bowels, and redness of the urine. After continuing for some hours these symptoms may subside, and the animal commences to eat and ruminate. The febrile symptoms, however, often return, and in the end the sufferer too often succumbs.

In another form of anthrax without external tumours, the most prominent sign, in addition to the general disturbance, is the passage from the bowels of quantities of dark-coloured blood; and the disease is then denominated enteric or abdominal charbon, the post mortem characteristics being congestion of the intestinal mucous membrane, more particularly in the small intestines, which are covered with petechial spots, with incipient ulceration in their centres, extravasation of dark-coloured blood into the canal, and very often extravasations into the sub-lumbar areolar tissue; the fatty mass surrounding the kidneys being loaded with extravasated blood, in a disintegrated, broken-down, tarry, semi-fluid condition, or covered with petechiae.

**Symptoms of Symptomatic Anthrax, or Anthrax Fever with External Manifestations — Gloss-Anthrax — Blain — Quarter-Ill—Black-Leg, Etc.—Charcot’s Disease.**

**Black-Leg — Quarter-Ill — Black-Quarter.**—This form occurs usually in young animals under eighteen months or two years. It often kills suddenly, but generally there are some indications of its progress. It is due to a bacterium differing in its specific effects from that of splenic fever. Experiments conducted by
Arloing, Cornevin, and Thomas demonstrate in the clearest manner that the injection of the specific bacteria into the blood, care being taken to prevent their introduction into the areolar tissue, causing a slight and evanescent illness, confers a complete immunity against future attacks of the disease, but does not render the animal proof against splenic fever.

Twenty-five cattle were collected at Chaumont; thirteen of these had been inoculated by intravenous injection with the virus of symptomatic anthrax nine months before, the other twelve had not. All were inoculated with symptomatic anthrax in the cellular tissue. Of the twelve unprotected animals nine are dead and two others are ill. Only one resisted the inoculation, and it was found that this animal had been, during the previous year, in a stable which was visited by an outbreak of the disease. Of the thirteen protected animals only one presented slight pyrexia, lasting a few hours; in the others the inoculation was absolutely without effect.

In addition to demonstrating the efficacy of protective inoculation, MM. Arloing, Cornevin, and Thomas have studied the cause of the immunity of bovine adults in localities in which the disease is prevalent, and the result of their investigations has been communicated to the Paris Académie des Sciences.

Both in Britain and on the Continent of Europe it is well known that this form of anthrax attacks cattle between one and two years old, and it is also well understood that older animals are seldom or never attacked; and these observers ask, Is this immunity a simple consequence of mature age? Against this hypothesis is the fact that the law is true only of animals bred and born in a locality in which the disease is prevalent. In Algeria, where the animals are moved about from place to place, this immunity is not observed, and in rare cases of adult animals being attacked in infected districts, it is always found on investigation that these animals come from an uninfected part. Hence it seems probable that most young animals which live in an infected district suffer from the disease, but many of them in a benign form, and perhaps from repeated trivial attacks immunity is obtained. To ascertain if this is true, three animals were selected for experiment. One was a cow ten years old, the only surviving animal of fourteen which had been born on a certain farm, all the others having died from
this disease. Of the other two animals, one had been reared under similar conditions, while the second came from a district where there had been no disease for eighteen years. All were inoculated. The last died in fifty hours; the other two continued well in spite of a second inoculation.

An opinion prevails in this country that a certain disease in sheep, known as loping-ill or trembling, only met with in certain districts, is much more fatal to sheep brought from uninfected districts than to those which have been reared upon lands where the disease prevails. This disease is now being investigated, but owing to the absurd law against vivisection, experiments to prove or disprove the correctness of this opinion will be an offence against the law, unless indeed it be deemed wise and expedient to relax it for the solution of such an important problem.

Pathology and Symptoms.—The victim, which before the attack has generally been thriving rapidly, and is usually looked upon as the best of the herd, becomes listless; has a vague expression about the eyes; the ears become heavy and pendent; the animal is tender about the loins, ribs, and flanks; the pulse irregular, feeble, sometimes extremely so, rapid, from 80 to 120 per minute; the mouth hot and dry; the conjunctivae are often very much reddened, and sometimes spotted with petechiae. In the course of a short time enlargements form about the loins, back, neck, head, brisket, or upon one or more of the limbs, in which case the animal is lame. At all times there is an unwillingness on the part of the animal to move about; it seems stiff and rigid in the limbs, lies down much, and is unwilling to rise. The appetite is entirely lost, rumination suspended, the bowels constipated, and the urine scanty and high-coloured, sometimes dark or coffee-coloured. The swellings, when pressed upon, evince but little or no sensibility, are cold to the touch, and if the disease has existed a few hours, crepitate when handled. The symptoms of depression increase very rapidly; the prostrate animal is unable to rise from the recumbent posture; very often becomes convulsive; unconscious to surrounding objects, with fixed, staring eye, and vacant countenance, and dies in a state of coma, or, in other cases, from sheer exhaustion of the heart's action, with scarcely any visible nervous disturbance.
The tumours which form in the subcutaneous areolar tissue contain serosity and extravasated blood; they speedily decompose, during which process gases are evolved, giving rise to the crepitating sound emitted when the parts are handled.

In some instances, there are premonitory indications of disease before the intense febrile disturbance and subcutaneous extravasations are developed. Thus it is sometimes seen that when one or more animals die of quarter-ill, many in the same herd become unthrifty, lose flesh, are hide-bound, with arched back, stiffened movements, and elevated temperature. There is irregularity of the bowels, and high-coloured urine, capricious appetite, and irregularity of rumination. The skin in these cases is harsh, and covered with spots; and if there be no alteration in the diet and no remedial precautions taken, the graver symptoms become manifest, and the animals die.

Bollinger, who has studied this form of disease, has arrived at the conclusion that it is neither a form of anthrax, nor a septic or putrid infection, but it may be considered as a mycosis of the most dangerous kind, which always terminates fatally. Rabies may also be looked upon as belonging to the same class, though it differs from it so far as rapidity of course is concerned. The infecting element is, in all probability, a motile cryptogam (an arogenous bacillus) which is endogenous in the body of the diseased animal; and—with regard to its enzootic prevalence on certain pastures—it is also ectogenous. The disease, like anthrax, belongs to those diseases which may be transmitted by the soil. Considered with regard to its transmissibility, it is not contagious. Therefore the term "miasmatico-contagious" is just as inadmissible when applied to this disease as it is to anthrax. The infecting material is not only active when introduced into the subcutaneous tissues, but also when it gains access to the intestinal tract—as is also the case with anthrax. The disease can be artificially transmitted to cattle, sheep, goats, rats, and mice; though cattle are only spontaneously or naturally affected during its enzootic outbreaks. When animals are infected through the digestive canal, the disease may run its course without local manifestations, as a pure haemotnosis—much the same as with the exanthem of variola or anthrax without localisation. As a scientific designation for the malady, he recommends the employment of "Emphysema infectiosum."
Gloss-Anthrax, Blain, and Anthracoid Sore Throat are forms of the disease rarely witnessed since the modern system of draining land has been introduced, but in which the local manifestations are swelling, blackness, and mortification of the tongue, or of the structures of the throat. To these forms of charbonous disease of the ex may be added gangrene of the lungs, which may occur as a consequence of the continued circulation of blood altered in its constitution. I have not noticed this as a primary but as a secondary condition, occurring in animals which were recovering or apparently recovering from mild attacks of the disease. The symptoms were as follows:—About the tenth day after illness had been first observed, and after the urgent symptoms had disappeared, the breath became very fetid, the respiratory movements much accelerated, and the animals rapidly sank. The autopsy revealed the lungs in a state of gangrene, loaded with black, tarry, and decomposing blood, and the lung structure emphysematous from the evolution of fetid gases.

SYMPTOMS IN SHEEP. 1

In this country anthrax in sheep assumes the enteric form, but on the Continent of Europe splenic apoplexy seems to be the form by which they are usually attacked.

Anthrax in sheep is known in this country amongst sheep farmers and shepherds by the terms Braxy, Striking of Blood, The Blood, &c., and the first symptom exhibited by a sheep affected with braxy is a short step. This is discernible before they begin to lie down and rise frequently, or stand apart with the head depressed and the back arched, the disease having by this time made considerable progress. The contracted step is occasioned by pain in the bowels, as it is observed before any swelling takes place to cause an impediment in walking. "I have tested hoggs at night by this symptom, or had suspicions that they were affected, and in some cases they were dead in the morning; while in others they were only advanced to the next stage, which I have mentioned, either lying down and rising alternately, or standing apart with the head and ears hanging down, the eyes dull, the belly swelled, and the back arched."—(Mr. Cowan's Prize Essay on Braxy, Highland and Agricultural Society's Transactions, 1863.) Should the disease

1 I have very great doubts about the correctness of this view of the pathology of braxy, and am disposed to conclude that it is a form of septicemia.
not terminate rapidly, and the animal hold out for some time, the wool begins to fall and to have a dry appearance.

The *post mortem* appearances are analogous to those seen in cattle, namely, a great tendency to rapid decomposition of the blood and tissues; the blood-vessels are full of dark semi-fluid blood; bloody froth issues from the nose, mouth, and sometimes anus; the flesh has a dark red appearance; petechial spots are visible upon the serous membranes and in the subcutaneous tissues; the abomasum and duodenum are highly congested, and covered with large dark-coloured spots of ecchymosis; the alimentary matters are mixed with blood, and the mucous membrane generally infiltrated in its substance, and coated on its surface with a layer of semi-coagulated, dark-coloured blood. The peritoneal cavity is generally filled with serum, and the bowels distended with fetid gas.

For much valuable information on the local causes of braxy I would refer the reader to the paper by Mr. Cowan, already referred to.

The other form of charbonous fever in the sheep, not commonly met with in this country, but which seems common on the Continent, is splenic apoplexy, the symptoms of which are similar to those witnessed in the ox. Indeed it may be mentioned that the malady in all its forms may be accompanied by splenic congestion. I have, however, witnessed instances of undoubted septic or charbonous disease in which no local lesion could be detected *post mortem*, the victim having evidently died from the empoisoned condition of its blood, before local manifestation had had time to become developed. The darkened colour and fluid condition of the blood and the proneness to rapid decomposition are always present.

In lambs charbonous fever is accompanied by external manifestations—swellings; and from the fact that the umbilicus is often involved in the tumefaction, the disease has been called “navel-ill.” It by no means follows that the external swellings are confined to the umbilical region, as they are frequently found in other parts of the body, and are of a similar character to those seen in young cattle. Indeed “navel-ill” is more appropriately applied to an inflammation of the umbilicus, which occurs conjointly with or independently of disease of the articulations in foals, calves, and lambs.—(See Septicæmia, p. 103.)
ESSENTIAL CHARBON, OR THAT ARISING FROM INOCULATION—
MALIGNANT PUSTULE (PUSTULA MALIGNA) IN MAN.

Definition.—The result of a specific poison implanted on some uncovered part, which produces in the first instance a redness like the bite of a gnat, and afterwards a minute vesicle. A peculiar form of gangrenous inflammation is excited, which rapidly spreads from the point first affected to the neighbouring tissues. Hardening and blackening of the part is so extreme, and death of the tissue is so entire, that the part cracks when cut with a knife. No pain attends the incisions; crops of secondary vesicles form round an erysipelas-like areola, chains of lymphatics become inflamed, the breath fetid, and death follows, amid all the indications of septic poisoning.—
(Dr. Wm. Budd.)

Such is the disease in man, and its identity with charbon has been satisfactorily proved by the fact that, when contracted by man, it has been communicated by inoculation to the lower animals. Malignant pustule in man is concurrent with charbon in cattle, &c., and is a result of direct inoculation. Other cases occur in which the exact vehicle of the poison cannot be identified, but these cases have all this significant peculiarity, that the disease is always seated on some part of the person which is habitually uncovered.—(Aitken.)

Propagation.—The disease may be communicated to man in the following ways:—By direct inoculation, as in the case of butchers and others employed to skin the carcases of animals which have died of charbon, the poison finding access by means of the skin or hands or arms of the operators; by means of the skin or hair of animals dead of charbon; and there are many examples related by Dr. Budd which clearly prove that the virus, when once in a dried state, may retain its virulence for an indefinite period of time. Trousseau relates that in two factories for working up horse hair imported from Buenos Ayres, and in which only six or eight hands were employed, twenty persons died in the course of ten years from malignant pustule. The disease may be communicated by eating the flesh of animals killed while affected with it, as also by using the milk and butter of affected cows.

I have known of several instances in which pigs have died in
great numbers after having eaten of the flesh and offal of cattle which had died of quarter-ill and splenic apoplexy; and Mr. Borthwick, V.S., Kirkliston, has told me an instance which occurred in 1872, in which twenty-five pigs died in two days after having eaten the flesh of a bullock which had died of splenic apoplexy.

ANTHRAX IN THE DOG.

The disease seems only to be developed in this animal after it has eaten the flesh of animals which have died of the disease; but even then this is not the rule. Indeed, so far as my experience goes, the development of the disease in the dog, even after it has devoured uncooked anthrax flesh, has occurred in a minority of instances only. But numerous cases are recorded where dogs have perished from this cause; and it is only stated that dogs, after eating diseased flesh, have, by biting, inoculated other animals.

The most prominent symptoms are vomiting, colic, sanguineous diarrhoea, convulsions, and great prostration; the local manifestations are swelling of the head and throat, vesication of tongue and mouth, and the formation of a tumour on some part of the body, but notably on the head, usually about the lips, without any increase of temperature or sensibility, or change in the colour of the skin. In a few hours this tumour acquires a considerable development, occupying all the region in which it is situated. When it appears in the head, it gives the animal a hideous appearance, completely closing the eyes and extending all down the neck along the trachea, and rendering respiration so difficult and stertorous as to induce prompt suffocation. When the tumour acquires considerable dimensions, the skin covering it shows numerous circular ecchymotic spots of various sizes, of a reddish violet colour, and a gangrenous appearance, the largest of which correspond to the point where the swelling first appeared.

The post mortem appearances are similar to those observed in other animals, the engorgements of tissues and organs depending upon the localisation of the disease.

ANTHRAX IN THE PIG.

The observations of Klein having proved that the very fatal disease amongst pigs known as anthracoid erysipelas, the blue
sickness, pig typhoid, &c., differs in many particulars from anthrax; the varieties witnessed in the pig are reduced to anthrax fever, gloss-anthrax, and anthrax with tumour. Anthrax fever is as rapidly fatal in the pig as in other animals, destroying life in a very short time, with but slight manifestation of sickness, killing by shock. In milder cases, however, there is loss of appetite, sudden prostration, sullen appearance, hanging ears, painful and haggard expression, vomition of a coffee-coloured fluid, continual convulsions, paralysis of the extremities, rapid alternations in the heat of the body, highly injected mucous membranes, and generally terminating in death.

_Gloss-anthrax—Anthracoid angina._—This form of anthrax is most commonly seen in the pig when it has fed on the flesh of other animals which have died of the malady. It is rapidly fatal, the throat swelling enormously; the pharynx, larynx, tongue, &c. becoming enormously swollen and gangrenous; an exhaustive diarrhoea, with great tenesmus and discharge of blood, often appearing prior to death.

Anthrax with tumour, or, as it is called by Mr. Fleming, carbuncular anthrax, seems a very rare form in the pig. That author describes the tumour as appearing in "the laryngeal and parotideal region, and is deep-seated; it is connected with or dependent upon a peculiar condition of the bristles growing in this region. A tuft of these—numbering half a dozen to twenty—becomes invaginated in a curious depression, or infundibulum, that forms usually a little below the parotid gland on each side, and between the lower jaw and windpipe. The process of invagination goes on, the bristles become hard and brittle, and if the slightest traction is made on them the animal manifests indications of acute pain; at length they disappear entirely externally, and begin to press upon and even perforate the larynx, producing symptoms of asphyxia," &c.—(FLEMING'S Manual of Sanitary Science and Police.) Granting that such an inversion of the natural growth of the bristles might occur, I fail to see what connection it has with anthrax.

**ANTHRAX IN POULTRY.**

Charbonous fever is announced in poultry by the following symptoms:—No appetite; feathers ruffled; walk difficult and staggering; fetid diarrhoea; great prostration; dragging of the
wings; turgescence or blackness of the conjunctivæ; excessive sensibility of the extremities. The fowls squat, and do not look for a perch; the bill and comb become black; tumours, or red spots, which soon become black and gangrenous, form on the palms of the digits, and the animal dies in convulsions.

PATHOLOGICAL ANATOMY OF ANTHRAX.

Post mortem examinations disclose very manifest lesions, which explain the rapidity with which putrefaction has taken place in the tissues.

(1.) Exterior.—A short time after death the whole body is tumefied and disfigured from excessive formation of gas in the areolar tissue. The abdomen is considerably swollen from gas in the gastro-intestinal organs, and blood-clots escape from the nose and mouth; the rectum is reversed, and looks like a black tumour, from the centre of which gas and tainted liquids escape.

On different parts of the body, notably on the skin deprived of hair, red or mulberry spots, sometimes interspersed with yellow ones, are found.

After being opened, the body emits a very fetid odour.

(2.) Skin, cellular tissue.—In excising the skin crepitation is heard, which results from the disengagement of gas accumulated in the subcutaneous areola; black and liquid blood escapes from the parts cut with the knife.

On the tumours and engorgements the skin is found semi-detached, and its internal surface presents spots of infiltration corresponding to those seen externally, and the tainted skins are at these spots without consistence, and depreciated in value.

The areolar tissue is the seat of blood and sero-albuminous infiltrations of yellow, red, or black colour, which extend into the interstices of muscles and to deep-seated organs.

(3.) Muscular tissue.—Yellow infiltrations on the surface, and to a less degree in the bed of the muscles, in the form of lines which put the fibrillæ in relief. The muscular system generally is impregnated with black blood, which communicates this colour to the whole frame.

The normal adhesions of the muscles to the bones, tendons, and aponeuroses are so relaxed that one may detach them without much effort.
In the thickness of the muscular substance black spots are found from the escapement of blood. These morbid alterations are most marked in tumours and charbonous engorgements, constituting masses of serosity of a citron colour, which raise the skin, infiltrate the subcutaneous areolar tissue, and penetrate deeply into the organs of the body. Infected gas is disengaged from the surface of the divided tissues; here and there portions of the tissues are decomposed.

It is a remarkable and important peculiarity that in these vast engorgements no trace of inflammation can be found, no plastic material, no injections, no vascular arborizations, which characterise the inflammatory process.

M. Delafond has recognised the following microscopic particulars:—

(1.) That where tumours are situated the tissue is penetrated by blood globules deprived in part of their colouring matter.

(2.) That the red colour of the tissue is due to the escape of the haematin from the red globules.

(3.) That the serosity of the infiltrations is fibrino-albuminous.

(4.) That this serosity is associated with a great number of very little globules, abnormally indented on their surfaces.

(5.) That the areolar plates, in which this serosity is deposited, are slightly opaque from coagulation of fibrin.

The morbid lesions of the solids are evidently a consequence of the primitive alteration of the blood.

The large vessels—the aorta, vena cava, vena porta, the cavities of the heart—are filled with fluid blood reflecting a strong, dark violet tint, presenting no signs of coagulation. The walls of the vessels and of the heart possess a red colour, which resists washing, showing that the colouring matter has penetrated the tissues.

These alterations explain the formation of black spots, of effusions, of bloody extravasations, and of serous citron infiltrations on the surface and in the depths of the organs. At the same time the deficiency of fibrin renders the fluid incoagulable both during life and after death. The heart is flaccid, soft, and covered with bluish spots. The blood in both sides of the heart is black, liquid, and more abundant in the right than in the left side of that organ. When exposed to the atmosphere it retains its black colour, or is but very slightly reddened. Some deny that it changes colour at all.
The pericardium is covered with ecchymosed spots. The pericardial fluid reflects a red tinge, more or less marked, according to the time which has elapsed between death and the autopsy.

(4.) Lymphatic system.—The ganglia of the cervical region, of the thoracic cavity, of the dorso-lumbar and inguinal regions, are always diseased. They are much increased in volume, ecchymosed, yellow or red, soft, impregnated with a great quantity of serosity, and a citron-coloured infiltration, and are easily pulpified by pressure between the fingers.

These characters are found in a degree more or less marked in the lymphatic ganglia of all the organs; on minute dissections being made, cords and little nodules are seen of a yellow colour, and of various forms and sizes, and the lymphatic vessels, especially those that have the tumours, are much distended.

(5.) Digestive apparatus.—The peritoneum, epiploon, and mesenteries are irregularly covered by ecchymosed spots. The peritoneal cavity contains serosity of a deep colour, mixed with blood-clots. The large veins which follow the convolutions of the intestines have a bluish aspect, and are distended with very black blood. In the mesentery, and above all in the sub-lumbar region, charbonous tumours of various dimensions are found. They are very common in horses which have died of charbonous disease without external eruption.

The tumours are formed by a mass of very black blood of a syrupy and gelatinous consistence, and by an infiltration of serosity of a yellow colour. They are situated in the fatty masses that surround the kidneys, the pancreas, the posterior vena cava, the sublumbar ganglia, and between the folds of the mesentery, immediately above the convolutions of the intestines. The intestines present exteriorly a red colour, more or less marked, following the extravasation and escape of blood. The lesions found in the interior of the canal vary from a simple red discoloration to a dark congested state of the mucous membrane. When washed, the villi are seen congested and augmented in volume. In other cases blood is extravasated, and fills the intestinal conduit, mixing with the alimentary matters. It rapidly decomposes, and emits a bad smell. Under the mucous membrane a yellow infiltration is found, extending into the sub-peritoneal areolar tissue. Peyer's patches do not
present any characteristic alterations. In some cases the mucous membrane surrounding them has been seen to be ulcerated; and in animals of the bovine species the glands of Brunner have been seen to be augmented in volume.

(6.) Spleen.—This organ is the seat of very remarkable lesions, and in virtue of the general constancy of their character, they may be considered as the most conclusive expression of the existence of charbon. Its volume is often double, triple, or quadruple; it is larger, longer, and thicker, and its external surface has a livid blue or black colour. The enlargement is sometimes uniform, sometimes irregular, and is formed by a mass of blood distending the splenic capsule, which occasionally becomes ruptured, giving exit to thick, black blood.

When cut, black incoagulable blood escapes from the incision. On pressing and washing the tissues, the putrid matter is removed, and the fibres left are of a reddish-black colour.

(7.) Liver.—Augmented in volume, with the appearance of having been boiled. Its tissue is friable, easily cut, and from the cut surfaces great quantities of black blood escape.

(8.) Respiratory organs.—Some amount of serosity in the chest, of a muddy and slightly red colour. The costal and pulmonary pleurae are covered with black spots. In the subserous areolar tissue there is a yellow citron infiltration, which is continued into the interlobular areolar tissue. Gas is developed as in the subcutaneous areolar tissue, and brown and black spots are seen throughout the lung tissue and on the respiratory mucous membrane.

(9.) Nervous system.—The meninges of the brain and spinal cord are covered with black spots. The venous sinuses are filled with a very liquid blood, and in places yellow infiltrations are observed. The cerebral substance is ecchymosed, and clots of blood are seen on its surface.

The ganglia of the great sympathetic nerve are large, red, soft, and infiltrated.

(10.) Urinary apparatus.—Like the liver, the kidneys are augmented in volume. They are of a brownish colour, easily broken down, and the blood with which they are filled escapes when they are squeezed.

A consideration of the lesions found post mortem leads us to one conclusion—namely, that the alterations seen in the solids
are due to a profound modification which has been established in the physical and chemical characters of the blood.

In the horse more particularly, the jelly-like yellow and sero-haemorrhagic infiltrations are encountered nearly everywhere in the body where there is loose connective tissue, chiefly in the retro-pharyngeal and laryngeal tissues, along the course of the great blood-vessels of the neck, in the mediastinum, peritoneum, and about the kidneys. The corresponding lymphatic glands, especially the mesenteric, show sero-haemorrhagic infiltrations, are considerably enlarged, and here and there in a state of incipient gangrene. The intestinal lesions in the horse are for the most part not so diffusely spread; but still upon the mucous membrane, which is in a catarrhal state, oedematous, and sprinkled with ecchymosis, there are found well pronounced carbuncles, which are the seat of more or less superficial sloughs. The intestinal contents are likewise often bloody and thinly fluid. The large glands, liver, and kidneys as a rule are swollen, the parenchyma cloudy, succulent, and full of blood. In the blood, besides the presence of bacteria, the white corpuscles are found to be in considerable number. The red corpuscles for the most part are of lessened consistence, and manifest a tendency to cohere in little heaps. On microscopic examination of the carbuncles in the intestines, as well as elsewhere, and of the jelly-like haemorrhagic effusion into the connective tissue, there are found in the capillaries, which are considerably dilated, besides a massing of white blood corpuscles (cellular oedema), numerous bacteria, and a finely granular mass, consisting partly of metamorphosed blood detritus, and partly bacterial germs. The thickness of the blood is due to its being deprived of water by the dropical, jelly-like, and oedematous effusions. The dark colour is caused by carbonic acid poisoning.—(BOLLINGER.)

TREATMENT.

When the symptoms of the disease, in any of its forms, are fully developed, but little good can be effected by medical or surgical interference. Some few cases may, however, be amenable to treatment.

Locally the extravasations may be fomented with very hot water, and dressed with carbolized oil—one part of carbolic acid to four parts of sweet oil.
If the parts have become gangrenous, it is useless applying anything to what is already dead; but the surrounding structures may be stimulated, say with equal parts of liquor ammonia, turpentine, and olive oil. However, the local treatment is of secondary consideration, as the tumours are but the result of an altered condition of the blood, and it is to restore the physiological condition of this fluid that remedies should be directed. The blood is fluid, dark, imperfectly coagulated, containing the constituents which unite to form fibrin in a diminished quantity, or in an altered or modified condition. How, then, is the viscidity of the blood to be restored? Direct experiments upon the blood removed from the body, and the treatment of hemorrhagic diseases, have very satisfactorily shown that the chlorate of potash has a peculiar effect in this direction, and it is upon this substance that dependence must be placed. For young stock the following draught is to be administered:—

\[ Rh. Pot. chlor. ii. \]
\[ Aqua, \]  10.

M. and give three times a day.

For a full-grown animal an additional drachm may be given with safety; but if given in large doses intestinal irritation is apt to be induced.

It has been already stated that carbolic acid causes the immediate disappearance of the *Bacillus anthracis*. On this account, and from its well-known antiseptic properties, it may prove very useful in the treatment of anthrax; indeed, I understand that Principal Veterinary Surgeon Collins has prescribed its internal administration with marked effect in India. It may be given largely diluted, two or three times a day, in doses proportionate to the species and size of the animal under treatment. M. Decroix, P.V.S., French army, recommends the borate of soda, 100 grammes daily, dissolved in water, and given as a draught to the horse.

Purgatives generally do harm, and for the reason that there is some congestion of the intestinal mucous membrane.

During the course of treatment of charbon it is important that special regimen be used. The animal should be well nourished. Food easily digested and of good quality should be given. Tonic medicines, as preparations of iron, gentian, and decoctions of aromatic plants, may be used at the time of convalescence.
The prevention of charbonous fever is a matter of great importance. Some writers affirm that it is more commonly met with since the introduction of artificial manures, and that it is due to the presence of the nitrites conveyed from the soil to the blood in the water, herbage, turnips, &c. I think that this view is not established, as the malady is met with where artificial manures are not at all used. If it were solely due to the nitrites or to any of the salts contained in artificial manures, its existence would have been unknown prior to the introduction of such manures. It is a fact, however, that when animals are poisoned with the nitrites, such as the nitrite of amyl, that the blood assumes a chocolate colour (Dr. A. Gamgee); and it is also a fact that certain diseases are more prevalent on rich than on poor soils. On this point Mr. W. Robertson, Kelso, makes some remarks which are well worth quoting. He says—"Speaking generally, the causes which tend to the production of this entire group of blood diseases, from which such numbers of our animals of all ages are lost, may be said to be associated—"

"(1.) With the characters and conditions of soil and its manurial richness, by which are materially modified both root crops and grass. They are more prevalent on rich lands when undrained, and on naturally dry soils in damp seasons when the temperature is high.

"(2.) With a state of plethora or redundancy of rich circulating blood in the animals themselves, more particularly when this advance in condition is preceded by a previous stinting or lowering; when the stock have been removed from a comparatively sparse diet, or one poor in nutritious materials, to decided abundance or of a highly nutritive nature.

"(3.) When this free supply of food is so provided that the animals have no necessity to take even moderate exercise in order to procure this, or for want of space it is impossible. This condition is extremely prejudicial to pregnant ewes, particularly as relates to progeny, and in them is a fertile source of that fatal congestive fever occasionally met with.

"Altitude and exposure, by which sudden checks are experienced from the rapid alterations of the weather. This is most noticeable in our most exposed sheep-walks, where it is well known a sudden change of weather, as an unexpected snow-blast, determines the production of many cases of braxy." He further adds—"Errors in dieting, and an absence of that just
relationship which ought to subsist between external local influences and the character of the stock reared, are the main causes of the occasional undue prevalence of these diseases.

"Stock-owners, in their anxiety to attain a given end, are too apt to forget that the laws in accordance with which healthy animal existence is maintained cannot be infringed without the penalty for this infringement being exacted in the form of a higher death-rate; that neither young animals, nor those which have reached maturity, especially if previously below par, can without risk be put at once upon a diet unrestricted in amount and increased as to its nutritive qualities, and this more particularly under certain influences of climate and locality."—(Hints to Stock-Owners, by Mr. W. Robertson, M.R.C.V.S., Kelso.)

Preventive treatment.—It is an undoubted fact that the introduction of setons is a very effectual preventive of charbon, and their operation is explained by the fact that in inflammations, artificially produced or otherwise, the coagulating properties of the blood are increased. The quantity of fibrin discoverable after the blood is removed from the body is appreciably increased.—(See Inflammation—Principles and Practice of Veterinary Surgery.) The safest and quickest method of creating an artificial inflammation is by inserting a seton in the breast—the seton to be deeply inserted, and in order to increase its irritating properties, it should be dressed with blistering ointment. If the disease has appeared amongst a herd before the veterinarian's attention is directed to any method of prevention, in addition to setons, the chlorate of potash is to be given, mixed with the animal's food or water, for several days, the diet in the meantime being restricted, and all circumstances likely to promote the malady fully inquired into and removed.

It is also essential, not only as a means of prevention, but after the actual occurrence of the malady, that the excretory organs be kept performing their proper functions, and for this end gentle aperients and diuretics should be employed. I have already pointed out the danger of administering drastic cathartics, but there is no reason why the bowels should not be gently opened by laxatives, such as linseed or castor oil. If during the course of the malady it is thought necessary to employ stimulants to rouse the flagging animal energies, the preparations of ammonia are to be avoided, as they cause the blood to lose its coagulating properties, both within and without the body; and,
as already stated, an excess of ammonia already existing in the blood, alcoholic stimulants are to be given in preference. Acting upon this conclusion, I at one time administered acid preparations, and with some success, but a larger experience has taught me that the chlorate of potash is superior to all other medicines.

The flesh of animals which have died or have been killed whilst suffering from the disease should not be used as food, either for men, pigs, or dogs, as it is apt to cause death by blood poisoning.

CHARBON UNDER THE REPORT OF THE FRENCH SANITARY POLICE.

The pathological study that we have given of charbon demonstrates that this malady is often developed spontaneously, and is susceptible of being propagated by contagion. It is not solely communicable to animals of the same species, but also to animals of different species, and even to man. The contagion, we should say, lies more particularly in the cadaveric body, and especially in the blood. The administrative measures for preventing the propagation of charbon are the following:—

1st. The proprietors or possessors of animals must declare its appearance.
2d. Isolate from those in good health.
3d. Avoid driving to drinks or pasturage.
4th. Remove the diseased, and do not allow them to come in contact with neighbouring cattle.
5th. Mark those that are affected.
6th. Do not sell to the butcher.
7th. Give the axe to those that are incurable.
8th. Bury the dead in deep pits, and at a distance of 200 metres from all habitations and ways of communication.
9th. Hide or bury the litters and alimentary matters in deep pits, or burn them.
10th. Ask the proprietors to disinfect those places that have been occupied by the disease.
11th. Forbid the consumption of flesh of animals that have been ill of charbon, and also of their milk.

These measures are implicitly and explicitly prescribed—

1st. By the decision of the Council of State of 10th April 1714, and of 16th July 1784.
CONTAGIOUS DISEASES.

2d. By warrant in 1791.

3d. By Articles 459, 460, 461, and 462 of Penal Code.

4th. Finally, by the direction of the Assembly, made on the Judiciary Organization of 16th and 24th August 1790, title ii. art. 3, which was entrusted to the vigilance of the authorities to prevent and arrest, by convenient precautions, epizootic and contagious diseases.

Use of the flesh of dead animals that have been sacrificed in the course of this malady.—The sale and consumption of such is strictly forbidden. The rapidity with which the flesh putrefies and becomes black after this disease opposes its public consumption. In all these cases the authorities have a right to prevent infringements of the law prescribed in sanitary regulations. This lawful defence considers public hygiene most powerfully, and the annals of science contain several facts which attest that men have succumbed after eating charbonous meat.

Of the use of milk of charbonous subjects.—Milk of animals affected is not allowed to be used, its physical character, being changed, rendering it unfit for the use of man. From the report of Chrisholm, a girl of three years, who had drunk of the milk of a cow affected, showed all the symptoms of a malignant charbon. The same took place in five members of a family.

TEXAN FEVER.

This disease has been described as anthrax by some writers, but whether it be so or not is as yet an uncertainty, as the name seems to me to be a favourite term applied in some parts of America to disease arising from a variety of causes—such as drinking alkali water, ticks, want of water during hot months, &c. Dr. Salmon, however, has performed some experiments, and appears to have proved that the disease is due to a peculiar micrococcus which is found in the spleen of the diseased animal, and that sound cattle may be successfully inoculated with material obtained from the diseased spleen, and thus brought into a condition to resist the effects which usually follow exposure to the contagion.

In Central America a charbonous disease has been investigated by Dr. Roy, Cambridge, who states that he has demonstrated that its virus may be attenuated by being passed through the prairie dog, and that cattle inoculated with this attenuated virus are enabled to resist the contagium.
CHAPTER XXVI.

CONTAGIOUS DISEASES—continual.

SWINE PLAGUE.

Pneumo-enteritis contagiosa (Klein); typhoid fever (Budd); also known as red soldier, blue sickness, measles, and erysipelas in this country; in America as hog cholera and intestinal fever. The disease undoubtedly simulates anthrax in its anatomical characteristics, but the observations of Professor Axe, as well as those of Dr. Klein, have proved that it differs from it in its incubative period, its general pathology, and in the anatomical character of the spleen and blood, and, according to Klein, from typhoid in its anatomical character.

Definition.—Swine plague may be defined to be a highly contagious and infectious disease, having a period of incubation, after inoculation, of about five days, at the end of which period there is elevation of temperature to 104° or 106°, succeeded by signs of general ill-health, and generally a rash on the skin.

When propagated by cohabitation, it appears, according to experiments performed by Dr. Lutton in America, that the disease took about thirteen days to manifest itself in healthy pigs amongst which diseased ones had been introduced.

The disease is very common in Great Britain, Ireland, America, and various parts of the world.

It prevails as an epizootic, and is the most fatal malady to which swine are liable; but pigs differ in their susceptibility to it.

Causes.—Like cattle plague, pleuro-pneumonia, &c., swine plague appears to arise from contagion and infection only; no amount of bad management, filth, want of drainage, nor decomposing food being sufficient of themselves to induce it; and it is held by some to be due to a rod-like organism, and by others to a microbe having a shape like the figure 8.
PATHEOLOGY AND SYMPTOMS.

The symptoms are loss of appetite, general prostration, small and frequent pulse, hanging ears, sullen appearance, painful and haggard expression, watery eyes, conjunctivae red and spotted, dirty secretion about the eyelids, generally preceded by a red blush and red spots on the ears, the abdomen, and internal aspects of the extremities.

The reddened spots are at first hot and painful to the touch, but afterwards become cold, humid, and insensible even to the pricking of a pin. As the disease advances, tremblings and convulsions are manifested, the animal grinds its teeth, the flexor muscles of the limbs contract, and the animal stands upon its toes. These symptoms are succeeded by paralysis of the posterior extremities, or of the whole body, involuntary defecation, and passage of high-coloured and even bloody urine. The bowels are at first generally torpid, but the fecal matters may be soft and mixed with very black fetid blood, and thick tenacious mucus. Diarrhoea, however, often sets in; the defecations are then profuse and exhausting; the breathing becomes catching and convulsive, a painful cough is present; the convulsions become more aggravated, and may continue to the end, or the animal becomes comatose, till death closes the scene.

In some cases the first observable symptoms remain stationary for a period varying from twenty-four to forty-eight hours; then the surface of the body becomes burning hot, and very sensitive to the touch, notably at the sides and abdominal walls. If touched, the animal cries with pain, and to these signs are added tremblings, convulsions, grinding of the teeth, and tetanic contraction of the muscles; succeeded by rapid diminution of temperature. The conjunctivae become brown; the eyes bleared; the tongue dirty, thick, and bluish; and the animal, extended on its litter, incapable of any regulated movements, succumbs in from twenty-four to forty-eight hours.

These symptoms are liable to various modifications, depending upon the intensity of the fever and the various localizations of the poison. In some cases, the virus seems to expend itself upon the serous membranes, inducing peritonitis or pleurisy; sometimes upon the mucous membrane, as expressed by bronchitis or broncho-pneumonic congestion and hemorrhage, enteric con-
gestion and ulceration, sometimes even to perforation or rupture of the bowel.

In many cases the animal is amaurotic, wanders to and fro, falls down, rolls and kicks, and seems to be in pain. Now and then it will rise from its bed and give a piercing cry, the whole body being involuntarily convulsed.

As a record of day to day observations, I beg to quote the following from the *Veterinarian*, August 1876, by Professor Axe, to whom thanks are due for his investigations:—

*Record of Experiments.*

"1. The object of this experiment was to determine if the contagion of pig typhoid could be transmitted from one animal to another through the medium of the atmosphere.

"For this purpose two pigs about six months old were obtained from a healthy herd. On the 21st of April they were put into a house with a diseased pig, brought to the College by Mr. Hussey of Devizes, and after forty-eight hours' exposure the diseased animal was destroyed. The healthy animals were placed some distance apart from the infected one, and the greatest possible care was taken to maintain complete isolation, not only with regard to the animals themselves, but also with reference to the excreta of the infected pig. The internal temperature was taken in the mornings and evenings throughout the entire course of the malady, and will be found recorded in the thermometrical table. I propose to describe the course of the disease as it appeared in the two pigs separately, and shall distinguish them as A and B.

*A.*

"April 28th.—Slight dulness is apparent, and the evening meal is refused, excepting the fluid portion of it, which is drunk with avidity.

"27th.—Dulness more marked, skin of face corrugated, and the countenance expressive of pain, seemingly referable to the head.

"28th.—The skin is hotter than natural, though no eruption is developed. The eyes are congested and suffused with tears. Food is taken sparingly, but water is drunk freely; pulse quick, soft, and weak; breathing very slightly accelerated.

"29th.—The temperature of the skin is increased, and a general redness is visible over the belly and on the inside of the arms and thighs and behind the ears.
"30th.—A few round raised spots of a red colour are visible on the breast and throat. Dullness is much increased, and a great desire for warmth is manifested. A watery discharge issues from the eyes, and dirt accumulates around them in black scaly masses.

"May 1st.—The discharge from the eyes is thick and puriform, and a watery secretion issues from the nostrils. The eruptive spots are still visible, but the general redness of the skin has subsided, and the heat is less intense.

"2d.—Signs of emaciation are present, and the movements are feeble. The spots are subsiding, and can only now be felt, the redness having disappeared. The general symptoms of illness are less marked, but the thirst is intense, and slight tremors are present.

"3d.—Much the same as yesterday.

"4th.—The bowels are constipated, and the faces streaked with blood and thick tenacious mucus. The lining membrane of the rectum is of a scarlet hue. More food is taken, and the thirst is less severe.

"5th.—Skin very hot, and the animal refuses food; the thirst increased, movements unsteady, and rigors are excited by the least exposure.

"6th.—A diffused redness is visible over the belly, which is most intense towards the centre; the inside of the arms and thighs is also red, but less so than the abdomen. Great prostration is now apparent, and rapid emaciation is taking place. All the other symptoms are aggravated, and the gait is unsteady.

"7th.—A fresh crop of spots has appeared, and the animal seems somewhat more cheerful, though he obstinately refuses food and drinks largely. The stools are soft and of a yellowish-brown colour.

"8th.—The face is pinched and very anxious; the eyes are bright, and the lids charged with puriform matter. The eruption is more extensive and decided. Great irritation is manifested by repeatedly scratching the abdomen. The bowels are very loose, and the stools more decidedly yellow.

"9th.—Diarrhoea acute, stools of a dirty yellow colour and watery. Prostration increasing. Food altogether refused, but thirst still great.

"10th.—Epidermis is desquamating from the seat of the early eruption, and slight moisture is observable on the surface of the
more recent spots. The stools are watery and frequent, and pain
is evinced on pressing the belly.

"11th.—Stools streaked with blood. Belly and inside of
arms and thighs intensely red and hot. The countenance
is expressive of stupidity, and slight twitchings of the muscles
are perceived at short intervals. The hind extremities are
partially paralyzed, and the body has a rolling movement.

"12th.—The skin exhibits a number of purple patches and
small petechiae. They are especially numerous on the belly and
the inside of the thighs. Thirst is very great.

"13th.—All the general symptoms are aggravated.

"14th.—Same as yesterday.

"15th.—Feces black and stinking. Conjunctival membrane
studded with petechiae; abdomen very sensitive. Nothing is
taken but fluids. A feeble grunt is constantly emitted with
each expiration, and complete paralysis is present.

"16th.—The feces are less fluid, and, excepting where the
blood spots and patches are, the skin is now much paler in
colour.

"17th.—Extreme prostration is present, and dissolution seems
fast approaching. The feces are mingled with blood and small
particles of soft grey sloughs. The entire body is convulsed, and
as the animal lies the legs are violently jerked towards the trunk.

"18th.—The convulsions continued throughout the day.
Animal died at six o’clock p.m.

B.

"April 28th.—Slight dulness is perceptible and the food is
dpartaken of indifferently. There is marked thirst, and the skin
is hotter than natural.

"29th.—Much the same as yesterday.

"30th.—The skin is intensely hot and of a deep red colour;
dulness is increased and the face slightly pinched.

"May 1st.—The red colour of the skin is less diffused, and
now the rash has appeared in irregular patches; the appetite is
very fastidious and the thirst intense.

"2d.—A watery discharge issues from the eyes and nostrils;
but in other respects there is no perceptible change.

"3d.—A few small red spots exist on the belly and on the
throat; dulness is more marked, the skin of the face is deeply
corrugated and the countenance expressive of pain. The movements are somewhat feeble, and rigors are present.

"4th.—A few more spots have appeared, and on some of yesterday's crop a little moisture is visible.

"5th.—Food is entirely refused, and the animal is evidently much weaker, the pulse is quick and feeble, the bowels constipated, and the discharge from the eyes and nostrils is assuming a puriform character.

"6th.—A fresh eruption of spots has occurred on the inside of the arms and thighs and behind the ears; they are very numerous and in some places confluent. The spots erupted on the 3d have entirely disappeared, leaving the epithelium raised and desquamating. Prostration is great, and shivering is excited by the least exposure.

"7th.—There is no perceptible alteration.

"8th.—The countenance wears a stupid expression. The conjunctival membrane is much injected, the skin is intensely hot, especially on the abdomen; the primary spots are turning of a yellowish-brown colour, but those of the second crop are subsiding.

"9th.—The prostration is very great, and the gait unsteady. The spots have nearly entirely disappeared. On the inside of the thighs are two large vesicles, and two others are on the breast. Diarrhoea is now present, and the feaces are very offensive; the skin is much cooler and less red than at any time during the eruption. The tips of the ears are of a bluish-red colour.

"10th.—The vesicles are increasing in numbers and some are confluent; there is considerable emaciation, and the slightest exertion gives rise to a fit of coughing; there is every indication of pneumatic complication.

"11th.—Vesication is extending, and large layers of epidermis may now be removed from the seat of the confluent vesicles. Diarrhoea is very acute, the stools are of a yellow colour, fluid and offensive. The animal rises with difficulty, and rolls from side to side in progression. Vision is much impaired. The breathing is quick and panting. Pressure to the abdomen excites struggling and squealing; the latter is very feeble and plaintive and attended with coughing.

"12th.—Emaciation is rapidly increasing, and there is complete prostration, with low delirious grunting. The skin is
Swine Plague.

Turning purple in patches, and petechial spots are scattered over the abdomen. Some of the vesicles are refilling. The extremities are cold, and the breathing is quick and hoarse.

"13th.—This animal died after being in a comatose condition for several hours.

</table>

*This table dates from the day prior to that of exposure.*
The condition of the blood differs in a marked degree from that of anthrax, being fibrinous, red in colour, and as a rule contains neither bacilli nor the contagium of the disease.

The experiments of Klein point to the conclusion that—"1st. The fresh blood of diseased animals does not, as a rule, contain the virus, as it fails to produce the disease when introduced into a healthy animal.

"Four animals were inoculated (at different times) with the fresh blood of diseased animals. They remained healthy. When subsequently inoculated with virus-containing matter, they became smitten with the disease.

"In a fifth instance, however, fresh blood did produce infection. [And this same blood proved active after having been kept sealed up in a capillary tube for several weeks.] This blood was obtained from a very severe case with copious peritoneal exudation; in which were found peculiar, abnormally large, coarsely granular cells; the same cells were also present in the blood; so that it appears probable that the blood became charged, by absorption during life, with matter from the peritoneal exudation. This latter always contains the virus in an active state.

"2. Experiments showing that fluid as well as solid lymph of the diseased peritoneum contains the virus in a very active state.

"Six successful inoculations with fluid peritoneal exudation.

"There is no difference of activity to be noticed between fresh exudation and one that had been kept sealed up in a capillary tube for several weeks.

"Solid lymph obtained from the peritoneal cavity of diseased animals, having been dried at a temperature of about 38° C., proves very active.

"3. Experiments showing that parts of the diseased lung, ulcerated intestine, and also diseased spleen, contains the virus in an active state. Diseased parts of lung or intestine that were dried at a temperature of about 38° C., retain their virulence unaltered.

"In all cases of pneuma-enteritis, the trachea as well as the bronchi have frothy blood-containing mucous matter, possessed of infectious properties. It must be therefore supposed that the breath of a diseased animal is charged with the poison. On
account of the diseased state of the intestine, also the dung is to be regarded as infectious.

"4. Experiments showing that infection is produced by cohabitation with a diseased animal, or by keeping healthy animals in a place whence a diseased animal had been removed.

"5. Several experiments were made to see whether feeding healthy animals on matter obtained from the diseased organs (intestinal ulcers especially) produces the disease. The experiment was always attended with success, if a lesion-abrasion existed in the mucous membrane of the mouth or pharynx; this was usually the case when the matter had to be introduced into the mouth while the animal was being held by assistants.

"There were, however, two cases which appear to prove that the disease cannot be produced by simple feeding.

"This was unfortunately at a time when I was not as yet acquainted with the fact that in many animals the disease is of so mild a form that it can hardly be recognised in the living animal. I have not made any post mortem examination of those two animals.

"But since then I have made two other experiments, in which the virus was brought directly into the stomach, by means of an india-rubber tube introduced per fauces and cesophagus. In both these instances the animals became diseased, and their intestines were most conspicuously affected.

"From the last three series of experiments, we may conclude that the principal way in which contagion of pneumo-enteritis is carried out, is through the instrumentality of the air and the food.

"6. This series comprises experiments to prove that the virus can be cultivated artificially—i.e., outside the body of an animal; in the case of splenic fever it has been successfully done by Dr. Koch.

"The experiments are seven in number:—(a.) Two refer to cultivations commenced with fluid peritoneal exudation; (b.) In the five others the virus had been obtained by cultivation of dried lymph from the peritoneum of an animal suffering from the disease.

"(a.) The cultivation of the virus for the first two cases was carried out thus:—

"Fluid peritoneal exudation of a diseased animal had been
collected and sealed up on November 6th, in a capillary glass tube. On the following day there was present a small clot due to coagulation. A minute speck of this clot was removed with the point of a clean needle, and with it was inoculated a drop of fresh aqueous humor of a healthy rabbit. This drop had been placed on a thin covering-glass, which, after the inoculation, was inverted over a small "cell," made by fixing a glass ring on an ordinary glass slide. The covering-glass was fastened on the glass ring by means of a thin layer of pure olive oil. The preparation was then kept in the incubator for twenty-four hours at a temperature of 32° to 33° C. After this time it was used to inoculate a new drop of aqueous humor in a similar manner to the one just described. We will call this the second generation.

"This new specimen was placed in the incubator, and kept there at a temperature of 32° to 33° C. for another twenty-four hours. In the same manner a third generation was started, by inoculating a fresh drop of aqueous humor. After having been kept in the incubator for several days, it was used to inoculate two animals at different times. Both animals became infected with the disease.

"(b.) The other five experiments were carried out with virus cultivated from solid lymph of the peritoneum of a diseased animal. The lymph had been dried at 38° C. (see series 2). A small particle of dried lymph is crushed into fine powder. With a granule of this, a drop of fresh aqueous humor is inoculated in the same manner as above described,—first generation.

"After having been kept in the incubator for two or three days at a temperature of 32° to 33° C., it is used to inoculate a second generation, care being taken to use a trace only of the fluid part, and not to come in direct contact with the original granule, which may be still discerned in the preparation.

"The specimen representing the second generation is kept in the incubator for a day or two. It is then used to inoculate a fresh preparation,—third generation. And, finally, this is used for establishing a fourth generation. After having been kept in the incubator, a part of it is used for inoculating two animals, the inoculation being carried out at different times.

"Both these animals became affected with the disease. Another portion of this fourth generation was used to start a
fifth generation, then a sixth, a seventh, and an eighth generation. With this three animals were inoculated at different times. All three animals became diseased in due time.

"In order to correctly interpret the results of the last (sixth) series of experiments, it is important to mention that inoculation with dried lymph, diluted far less than would correspond to the third generation in the last-named experiments, is followed by a negative result.

"The microscopic examination of the cultivated liquids proves that these are the seat of the growth and development of a kind of bacterium, which has all the characters of *Bacillus subtilis* (Cohn). The bacillus in our case is a very fine and delicate rod, thinner than that described by Professor Cohn in hay infusion, and the *Bacillus anthracis* so thoroughly investigated by Dr. Koch.

"Our bacillus differs also in other respects from *Bacillus anthracis*, inasmuch as it possesses a moving period—the *Bacillus anthracis* described by Dr. Koch is non-moving. Like *Bacillus subtilis* of hay and *Bacillus anthracis*, our bacillus grows under favourable conditions into long leptothrix-like filaments, which occasionally form more or less complex convolutions.

"In these filaments highly refractive spores make their appearance. These become free after the disintegration of the original filamentous matrix. The fully developed spores of our bacillus differ from those of hay bacillus and anthrax bacillus, by being more distinctly cylindrical and much smaller. According to Professor Cohn (Beiträge zur Biologie der Pflanzen, ii, 2, 1876, p. 264), the long diameter of the spores of bacillus of hay and also of anthrax—for both are identical in morphological respects (i.e., p. 275)—amounts to 0.0015—0.0022 mm., or \( \frac{1}{10,000} \) ths of an inch, whereas the spores of our bacillus are little less than 0.0005 mm., or \( \frac{1}{50,000} \) th of an inch, in their long diameter.

"At first I misinterpreted the spores, regarding them as a kind of micrococci, and only after repeated observations have I succeeded in tracing them through their different stages of development.

"After many failures—owing to the introduction and development of bacterium termo—I succeeded at last in obtaining, already

---

1 The experiments of Dr. Comar Kwart have since proved that the *Bacillus anthracis* has a moving period.
in the second generation of original virus, a pure crop of bacillus and its spores. With these I started several separate cultures, in which the germination of the spores into delicate bacillus, the swarming stage, the rapid multiplication by division, their growth into long apparently smooth filaments, and, under sufficient access of air, the formation of the bright cylindrical spores could be distinctly traced. (No other organisms appeared in these cultures.) These were again used to inoculate other preparations of aqueous humor, and so on, until I succeeded in obtaining considerable quantities of liquid, containing only bacillus and its spores. The last-named animals were infected with liquid of this kind.

"Seeing that splenic fever, pneumo-enteritis, and specific septicemia possess a great affinity in anatomical respects, and seeing that in splenic fever and pneumo-enteritis the materia morbi is a definite species of bacillus—the difference of species being sufficiently great to account for the differences in the two diseases—we may with some probability expect that also the third of the group (viz., specific septicemia) is due to a bacillus. This, however, remains to be demonstrated. It seems, finally, justifiable to speculate whether or not we have in these three varieties of disease 'a variation of species' in the sense of the evolution theory."

MORBID ANATOMY.

In the majority of animals, the skin about the perineum, groin, belly, and neck is swollen, and of a diffuse red or bluish-red colour, and the ear lobes and the skin of the nose also red and swollen, whilst in some instances there are gangrenous patches of the superficial cutaneous structures. In many instances, however, this redness of the skin may be entirely absent, even after death; but the longer the animal lives, the superficial structures become, as a rule, the more swollen, and the dependent parts of the ears become deep red, puffy masses, from the surface of which the epidermis peels off.

The blood-vessels of the skin are more or less filled with blood or plugged with fibrin, and around the vessels lymphoid cells are discoverable; the sudoriporous glands are greatly distended, and often filled with blood charged with large coarsely granular
cells containing large clear vesicular nuclei. The connective tissue of the corium contains fibrinous exudations and a yellow serosity.

The small intestines almost invariably, and the stomach more rarely, are congested and covered with spots of ecchymosis, both upon their mucous and peritoneal surfaces. The large intestines have always the most characteristic appearances. There are isolated or confluent, generally roundish, ulcerations at and around the ilio-caecal valve, the rest of the mucous membrane being congested and studded with spots of ecchymosis. Klein says the whole large intestine down to the rectum contains ulcers; in the caecum they are confluent, and measure several inches, extending transversely as well as longitudinally; while the whole remaining mucous membrane of the large intestine is much thickened, and in some parts the mucous tissue contains large accumulations of blood. The ulcers are of various aspects. The following forms may be seen—very minute, well defined, prominent yellowish-whitish specks of the size of a millet or hemp seed; then somewhat larger, more flattened, prominent, circular or oval, yellowish patches (with which in one case the whole mucous membrane of the caecum seemed quite covered) of the size of a hemp seed, up to about one-eighth of an inch in diameter; next, flat, circular, or slightly oblong patches, situated on the crust of a fold of the mucous membrane, in size from one-eighth to one inch in diameter, generally black or grey (from bile pigment), except a very conspicuous, and, I may almost say, characteristic prominent rim, which is yellow. The ulcer generally shows a pale central or eccentric disc, around which the rest of the ulcer is arranged as concentric rings. Between these flat ulcers with concentric layers, and those uniform, yellowish-white, prominent patches and nodules, there are all intermediary forms. This is easily understood, if it is borne in mind that as the latter increase in size, the central part is transformed into that black or greyish mass. Besides these, there are very often formed on the surface of the mucosa minute whitish specks, just perceptible by the unaided eye. In one single instance have I seen ulcerations of the lower part of ileum. This case had exceedingly numerous ulcerations of the large intestines. The two ulcers of the ileum were quite different from the ulcers generally found in the large intestine, for they were oblong, deep pits, surrounded by a thick,
prominent wall of swollen mucous membrane, very much the same as ulcers of human typhoid. But under any circumstances the microscope reveals a marvellous difference between the two diseases; for in the pig these patches, whether nodules or ulcers, have absolutely nothing whatever to do with lymphatic follicles, whereas in human typhoid there is found in the first stage round, or generally oblong, prominent papules or patches of swollen lymph follicles, surrounded by swollen mucous membrane, after which stage the greater part of the swollen lymphatic patches dies, and is finally discharged as a slough, leaving behind a pit-like excavation bordered by a well-defined fringe of mucous membrane, which is neither thickened nor indurated.

Fig. 13.—Portion of caecum of American pig slaughtered at Liverpool, May 1870.

a. Ilio-caecal opening.
b. b. Ulcers in various stages.

g. Congested, generally swollen, of a dark red colour, or infiltrated with blood, black, soft, and pulpy; those in connection with the intestinal canal are not only swollen, but infiltrated with a greyish-white opaque-looking matter.

The condition of the glands is sometimes very slight to the naked eye, there being merely swelling, and an apparent congestion; but even here the microscope reveals bursting of blood-vessels in the cortical tissue, and hemorrhage into the lymphatic follicles and sinuses of that part, amounting in severe cases to total destruction of the adenoid tissue by blood. In severe cases the medullary sinuses, and partly also the medullary lymphatic cylinders, become filled with extravasated blood. In so far as this condition is similar to what is found in anthrax. "This state of the lymphatic system is very characteristic, and, combined with the disease of the intestine, is of paramount importance to the diagnosis."—(Klein.)
Respiratory organs.—In a large number of cases, the tongue, mouth, fauces, and pharynx are ulcerated, and sometimes gangrenous; the lymphatic vessels filled with micrococci; the lungs are generally congested in patches, with distinct mottling out of the lobes and lobules by oedema of the interlobular tissue, succeeded by hepatisation, at first red, subsequently opaque, or white specks or patches appear in the red substance, which, as they increase in size, become confluent. This is due to the fact that the bronchial tubes become gradually filled with a white, brittle, cheesy mass, progressing gradually from the finest ramifications on to the larger branches of the lobules and lobes. Finally the whole lobule is transformed into a discoloured, dry, hard, friable mass. The pleura of the corresponding part is of course inflamed, being in some cases exceedingly thick, and covered with false membranes. In severer cases, the greater part of one lung and portions of the other may be thus changed, and on the external surface there may exist smaller or greater ulcerations. Except in very slight cases, there is generally a certain amount of pleural exudation; and in severer cases the pleura contains a considerable quantity of a thick, offensive, yellowish or discoloured exudation. In some severer cases the pericardium is also inflamed, containing a large quantity of exudation, and its walls being much thickened by false membranes. The same is also the case with the peritoneum, this being in some cases hyperaemic in parts, or even covered with solid lymph and pus.

The spleen and liver are, in severe cases, dark in colour, enlarged, and the kidneys are sometimes changed, being hyperaemic and covered with petechiae, particularly in the pyramids and underneath the capsule, which is easily stripped off.—(KLEIN.)

In the Privy Council Order dated 17th December 1878, which is termed also the "Typhoid Fever of Swine Order, 1878," it is laid down that typhoid fever of swine, otherwise called soldier disease or red disease, shall be deemed to be a disease (under the Contagious Diseases Animals Act, 1878) for the purposes of slaughter and compensation, notice of disease, Orders of Council, power of police, and power of entry; and, also (under the Animals Order, 1878), for the purposes of movement and exposure, movement of dung, burial or destruction of carcases, and general provisions, as also for cleansing and disinfection.
CHAPTER XXVII.

ENZOOTIC AND EPIZOOTIC DISEASES.

The great characteristic feature of all epizootic diseases is their tendency to spread rapidly, attacking large numbers of animals in a short space of time, destroying many and incapacitating a large majority.

The term epizootic is derived from the Greek, Επί, upon, and Ζώον, an animal. Diseases of this order are said to arise from enzootic influences—from Επί, in, and Ζώον, an animal. Enzootic influences are those peculiar to certain districts, and result from conditions or agencies peculiar to a locality, which favour the development of various miasmatic diseases, such influences becoming epizootic, or affecting the many, from causes as yet unknown. In this order of diseases may be included the catarrhal fever or influenza which prevails more or less at all times amongst the horses of large cities and certain localities. Such diseases may be said to dwell in certain localities, having, however, the tendency to spread rapidly. They are then said to be epizootic.

The subject of the origin, cause, and progress of epizootics is one which has been deeply considered. Speculation upon it has, however, proved but little, and all that has been proved may be summed up as follows:

That the causes of epidemics are due—"(1.) To general factors; that is to say, the working, separately or combined, or insufficiently balanced, of earthly forces more or less present, and varied by circumstances, such as air, excesses of heat, cold, damp, decomposition of organic matter, famine, crowding.

"(2.) The generation of a noxious substance or influence by an extraordinary conjunction of these general factors, which influence does not pass away when the conjunction ceases; a diffusible poison, indefinitely permanent or transitory."
"(3.) Direct contagion, or communication from person to person.

"(4.) Indirect contagion, or the poisoning, by the agency of an influence elaborated in the body, of media presented by houses, soils, water, and the like, which thus become the foci of disease.

"As to the nature of the infecting noxious influence, the adherents of the last two classes may be divided into such as favour—(1.) The theory of ferments; (2.) That of organic germs; and (3.) The theory of bioplasm."—(Cause of Epidemics, British and Foreign Medico-Chirurgical Review, October 1873.)

To each of these etiological explanations there are weighty objections, which are discussed at length by the writer of the above quotation. He says, the immediate action of common factors is shown first and most prominently on the weakly, sickly, least perfect members of the community, and if the action is not powerful, on them alone. But that is not the case with the diseases that are liable to assume an epidemic character. Very often the robust and well-to-do, in spite of being in a minority, are the first to suffer, and when they are attacked they run the most danger. The foregoing and the like considerations have led to the hypothesis that, from extraordinary combinations of common factors, a new matter, or at least a new influence, is generated, which survives its parent for an indefinite period, and is the immediate cause of the disease. If the common factors are powerful and generate it in large quantities, its consequences are broadcast and epidemic; if they be weak and in small quantities, sporadic cases only occur. The varieties of circumstances and places, of organic and inorganic constituents, will sufficiently account for the variety of epidemics, for the disappearance of old and the birth of new diseases. This is the hypothesis of morbid poisons, and the worst that can be said of it is that it is an hypothesis. And the main difficulty in the acceptance of this theory for all epidemics lies in the history of the diffusion of the poison. If it be spread by the air, how is it that the diseases travel sometimes against the wind? If by the water, how do they mount up stream to a higher level? How do they spread from the coast to the interior?

Add to this the confession that the researches of chemists and microscopists have hitherto failed to detect the presence of
any peculiarly noxious substance during epidemics, yet the
number of individuals attacked would lead to the supposition of
its existence in enormous quantities.

These difficulties lead to the pretty general adoption of the
doctrines of the "contagionists." They believe that the most
important element in the spread of epidemics is the living body
itself. Here the poison is multiplied; and incorporation with
the body is, if not essential, at least the most usual mode of the
poison's increase. But the main objections to the hypothesis of
contagion are—

(1.) The difficulty of obtaining positive evidence of it.

(2.) The fact that at the beginning of epidemics so many are
attacked at once.

(3.) The suddenness of the attacks, and sometimes of the fatal
event, seems opposed to the idea of multiplication, which
requires time.

(4.) It has been argued that if poisons multiplied in the body
at the expense of its substance, the process must needs go on as
long as life lasts, or as long as any substance remains to afford a
nabulum.—(PARKIN, p. 41.)

(5.) The fact that there are so many who are apparently
exposed to the supposed contagion, yet escape, at the same time
that others who avoid contact are attacked.

(6.) Bad consequences of social and financial character have
ensued in a belief in contagion.

(7.) The measures founded on the belief have often been un-
successful.

(8.) It is illogical to assume the existence of that which cannot
be made evident to the senses.

Stimulated particularly by the last objection, the chemists
and microscopists have exerted themselves vigorously to solve
the problem.

The directions in which they have speculated may be called—
(1.) The ferment theory; (2.) The organic germ theory.

In support of the ferment theory, it is argued that in zymotic
diseases there is an intensity of oxidation of tissues, a proneness
to dissolution and destruction very akin to what we call decom-
position. Furthermore, the rise in temperature in fevers cannot
but suggest to a chemical mind an increase of chemical inorganic
action; and the idea is strengthened by seeing new morbid
compounds which are formed become rotten more hastily than in health; e.g., the stools are abnormally fetid and changeable in colour, the urine soon becomes ammoniacal, the minute anatomical forms in tissues and secretions melt down and swarm with new movement, in the shape of bacteria, &c., with extreme rapidity. All this is so highly suggestive of what is seen in dead organic matter, in consequence of the introduction of other organic matter in a state of molecular change—i.e., of a "ferment"—that one cannot but suspect the presence of a "ferment" also as the cause of the diffusion of spreading plagues.

The most weighty arguments against this "zymotic" theory are—

(1.) That the analogy is too vague, and that there are too many gaps in the stretch left to be filled up by a staunch faith or an active fancy.

(2.) Nobody has found either the ferment itself, or the material whose decomposition is induced by the ferment.

(3.) There is no proof of increase of quantity in the infecting agent, since many poisons act in extremely small quantities.

(4.) In some "zymotic" diseases, as, for example, inague, there is evidently no multiplication of the infecting agent in the patient's body.

(5.) The action on the blood of animal poisons whose action can be traced, as, for example, that from a dead body or putrilege, is not fermentative or self-multiplying, but simply chemical.

(6.) If there be really no fermentation, no practical good can come of provisionally supposing one, for the hypothesis does not explain the phenomena of fever.

(7.) Even should it appear that a molecular change, somewhat analogous to fermentation, takes place in the body affected with a "zymotic" fever, still there is no evidence that such change is an essential part of the fever. It may have, like decomposing matter, a secondary promoting influence without any specific action; that is to say, it may promote disease, but not one disease more than another.

(8.) Living substance is so different from dead substance, physiological forces from chemical processes, that it cannot be expected that the laws of one should be explained by the laws of another.—(Estettten, p. 53.)

The organic germ theory is the result of the observations
which led to attributing fermentation to the simple, yet seemingly independent and living, forms of matter which accompany its development. As the conversion of sugar into black damp and alcohol was carried from one vessel to another by the transfer of a minute mould, so might morbid processes be carried from one body to another; and microscopists sought diligently for special moulds suited to convey special diseases. Thus Dr. Salisbury, of Cleveland, Ohio, pronounced in 1865 that malarious fevers were traceable to the absorption into the system of the spores of a fresh-water mould which one sees tingling with a burnt-sienna line the edges of marshy pools (the gemiasma). He attributes the phenomena of intermittence to the ripening of successive crops of the vegetable, which, however, in ordinary age are retained within the body.

Foreign substances of a vegetable nature, moulds, zymes, slimes, cells, spores, and threads, are found in abundance among the worn-out tissues of both sick and healthy. Our faces and the coatings of our tongues are full of them, but they do not seem to do any harm or to give rise to fermentative or febrile action.

The "bioplastic" theorists, instead of making the material cause of specific disease a parasite as foreign as it is inimical to the host in which it settles, suppose that it derives its origin from flesh of a similar nature to that which it afflict.s.—(See ante, Origin of Contagious Diseases.)

These observations, tending as they do to elucidate the cause or origin of epidemic disease, cannot be said to be satisfactory. What we actually know about them is that the first effects of an epizootic outbreak are the most violent and destructive, the disease becoming mild as the epizootic influence passes away. Epizootic diseases may entirely disappear after a short prevalence, and reappear after an indefinite period. They may, on the other hand, continue with irregular abatements for a number of years, and then give place to a disease of a different type. This change of type has occurred repeatedly during the last twenty years. At one time an epizootic disease of the mucous membranes has prevailed; at another a disease of the serous membranes; whilst during another period the epizootic influence has caused disease of the connective tissue and articulations.

The origin of the epizootic influence cannot be traced to any
known cause; and in the words of Dr. Wood, Pennsylvania, “all we can say with certainty regarding epidemics is, that there must be some distempered condition of the circumstances around us, some secret power that is operating injuriously upon our system, and to this we give the name of epidemic influence or constitution.”

That epizootic diseases originate independently of contagion or infection is a fact beyond doubt. It must, however, be admitted that an epizootic disease is sometimes conveyed from one locality to another by animals which are or have lately been suffering from it. This method of propagation is certainly not the rule, but it is not a very rare exception. On the other hand the rapidity of the spread, and the appearance of a disease in localities far apart, and between which there has been no animal intercourse, at once seem to negative any connection between animal intercourse and the propagation of the disease.

Epizootic diseases do not seem to follow the great lines of commerce. Nor is the main spread influenced by the wind, although some authorities would lead us to believe so; it does not travel with the same velocity, it often moves against it. It may, however, be carried by the wind for a short distance. Some observers advocate the vegetable origin of epizootics. Mr. Moorhouse of New York is of opinion that the American horse disease was due to this cause. He examined the matter exuding from the nostrils and mucous membrane of the affected animals; and besides the presence of pus and lymph-corpuscles and epithelium, found three kinds of vegetable organisms, all in states of vigorous development. One was a species of lichen, _Urecolaria acrposa_, which was so abundant that hundreds of fragments of this fungus were seen in every drop of matter examined under the microscope. Another was an unknown species of _Aspergillus_, also giving evidence of propagative growth. These spores were floating in the atmosphere in the immediate neighbourhood of the inflamed air passages. The observation, however, would have been more satisfactory if the discharges from a healthy animal had been examined, and the vegetable spores found absent. Even this would not have been conclusive, as the inflamed mucous membrane may have formed a favourable nidus for the germination of the spores.

The observations of Professor Jaa. Law are directly con-
tradicory to those of Mr. Moorhouse. He submitted the floating elements in the air from stables and fields to microscopic examination before and through the continuance of the American epizootic, without detecting any important difference in the floating germs and particles from first to last.—(Veterinarian, April 1873.)

Attempts have been made to prove, and beliefs have existed for many centuries, that vegetable parasites called "bloody snow," "blood rain," as well as the flights of locusts or insects, are common causes of epizootics; and in various parts of Mr. Fleming's book on the History of Animal Plagues we find this recorded. The matter is, however, well worthy of further study. At present it can only be said that no facts of any weight exist to connect an unusual development of vegetable fungi with the outbreak and spread of epizootics; and we must conclude with Dr. Pearson that "between the epidemic and the condition of the atmosphere there appears to be a connection different from that which depends on a mere alteration of temperature, or of dryness, or moisture; but what that peculiar connection is we shall not attempt to explain."

Epizootic diseases have been supposed to have a cyclical course, and to return pretty regularly in periods of years; and an ingenious theory has been propounded by Deputy Inspector-General Dr. Lawson to account for a series of oscillations of febrile diseases following each other over the world with amazing regularity. The mode of occurrence of such febrile diseases Dr. Lawson attributes to a cause or influence which, from its extent and progressive character, he names a "pandemic wave," to distinguish the influence from that usually understood as epidemic, which is limited to a single form of disease affecting a limited space. Under the influence of this pandemic wave, Dr. Lawson believes "that there is a constantly progressive tendency to the development of all endemic febrile diseases in the Atlantic and western parts of the Indian Ocean, from south or south-east to north or north-east." If this theory were true—if epizootic diseases were conveyed from place to place by this "pandemic wave"—we should expect them at pretty regular periods of time. But no regular period can be perceived. They may appear and commit their ravages, and then disappear for many years, or they may reappear in a few months.
In passing through a country they do not attack all parts of it. Country places are often spared, and sometimes large towns escape. They do not preserve any uniform line from east to west, or north to south, but travel about in a most eccentric manner.

This is not the case with those diseases epizootic in their extent and virulence, but which originate purely in contagion and infection. These diseases spread along the great lines of commerce, and are generally traceable from place to place with almost unerring certainty.
CHAPTER XXVIII.

ENZOOTIC AND EPIZOOTIC DISEASES—continued.

PANZOOTIC CATARRHAL FEVER, OR INFLUENZA.

An epizootic febrile disease, attended with great prostration of strength, and with early inflammation of the nasal, laryngeal, and sometimes bronchial mucous membrane, complicated with irritability of the digestive mucous membrane. Occasionally the disease implicates the substance of the lungs, pleura, liver, the fibrous structures of the articulations, theca of muscles and tendons, and the connective tissue of various parts of the body.

Synonyms.—Distemper; epidemic catarrh; epizootic catarrhal fever; (F.) coubrature, monfondure; (L.) febris catarrhalis, defluxio catarrhalis, &c. The disease was first called influenza in Italy in the seventeenth century, because it was attributed to the influence of the stars.

Panzootic catarrhal fever or influenza has a very early history, but to trace this would be beyond the purpose of this work. In 1299 it appeared in Seville, and is referred to by the veterinarians Martin Arrendondo and Fernando Calvo, who derived their information from Laurentius Rusius. It killed more than one thousand horses, and seemed to be incurable.

"In 1648 an epizootic broke out amongst the horses of the French army in Germany, and is described by Solneysell. It began by fever, great prostration, and tears running from the eyes, and there was an abundant discharge of a greenish colour from the nostrils."—(FLEMING.) In 1688 influenza was prevalent over the whole of Europe, affecting both men and horses. In 1699 Europe and America suffered from the disease, and again in 1732 it prevailed in both hemispheres. In 1767 it once more appeared in both hemispheres, and it is recorded that both horses and dogs were
liable to its attacks. In 1776, after a very severe winter and warm summer, with an earthquake in Wales, influenza spread over Europe, attacking horses and dogs first, and human beings after. Poultry died in great numbers of an epizootic with defluxion from the eyes. This epizootic was observed in Edinburgh in December, and in England at the commencement of January 1788. Influenza was very severe in New York, and caused great mortality amongst the horses of Maryland. During the present century the disease has raged with varying degrees of virulence in 1849-50, 1863-4; and the last outbreaks we have to record are—

_Influenza in London in 1871-72._—This outbreak was mostly confined to the English metropolis; it was of a severe but not fatal type.

_The American Horse Disease, 1872-3._—This disease broke out in Toronto, Canada, on October 1st, 1872. In nine days it had attacked nearly all the horses in the city, and carriages could not be had for any price. On October 18th it had reached Montreal, and was prevalent throughout Canada. On 14th October it had reached Buffalo; 17th, Rochester; 22d, Boston, New York, Brooklyn, and Jersey City; 27th, Philadelphia; 28th, Washington. It made its appearance in Nova Scotia on October 13th.

Mr. James Law warmly advocates the contagious origin of this epizootic. Mr. Greene, M.R.C.V.S., St. John’s, N.B., records the following important fact:—“I was always under the impression that influenza was both contagious and infectious till the late outbreak; since then I have altered my views with regard to the contagion and infection of that disease. One among several facts which I could mention will bear me out in this question.

“During the month of July 1872 a horse had been put to grass on Partridge Island, in the Bay of Fundy. This island is three miles distant from this city. No other horse had been near the island from the date of his landing up to the time of the outbreak in St. John’s, N.B., and on the 15th or 16th of October, which was only two or three days after the first case was reported in this city, the horse on the island was affected with the most violent form of the epizootic.

“Would not the morbidic matter have become diluted to such an extent (after travelling three miles) as to be inert?”—(Veterinarian, April 1873.)
ETIOLOGY.

The causes of influenza are very obscure. It may occur spontaneously in various places, but its first source of origin cannot be indicated. It does not depend upon any known condition of the atmosphere, nor upon soil, seasons, or temperature. It prevails on every soil and geological formation, sometimes more so in low-lying districts than on the hills. It may appear at all times of the year; perhaps it is more commonly seen in autumn, winter, and spring than in the summer. Very often, however, its worst form is seen during the hot summer months. Influenza has often appeared in foggy weather, but outbreaks have occurred without such a coincidence, and consequently no weight can be attached to this circumstance.

Its spread is not influenced by the wind; sometimes it moves against it.

"The outbreak of 1766 and the American one of 1872 succeeded to two very similar climatic conditions. The winters had been exceedingly severe and the summers unusually hot, and earthquakes had been frequent."—(LAW.)

Similar climatic conditions have, however, not been followed by an outbreak of influenza; and as in the case of fogs, mildews, &c., the coincidence can only be looked upon as accidental.

Sudden changes of temperature appear to assist the development of the influenza poison, and exposure to cold predisposes the animal to the disease, but neither of these causes is sufficient of itself to produce it.

Ozone in undue quantity in the atmosphere has been supposed to be a cause of influenza. This is, however, highly improbable, as ozone, although an irritant to the mucous membrane of the nose when applied in large quantities, has no effect on the nervous system like the influenza poison.

Whatever the specific material may be, it must exist in the air; it cannot be in the food or in the water. This conclusion leads us to two suppositions:—1st. That the agent is reproduced either in the air or in the bodies of the sick; and upon this point Dr. Parkes makes the following observations:—"It must be a specific agent of some kind. From the earliest times authors have come to this conclusion. The similarity of the symptoms in different epidemics show that this agent is the same in its
successive invasions. If it be connected with any unusual meteorological or atmospheric condition, this has not been detected, and it cannot be at present even guessed at.

"At the same time, this agent must be in the air; the diffusion is too rapid to suppose it to be conveyed by water; besides, water poisoning is usually localized. It cannot be attributable to food. There remains only the air as a medium of communication, and that this is so seems also shown by the way in which it can attack vessels at some distance at sea."

"There is, then, some special agent in the air. But this cannot be a gas; no gas could spread in this way without utter dispersion and destruction. Besides, the manner in which it is located in a part of a town, a street, or even one side of a street, for a time, or affects a town without touching a village a mile or two off, is quite conclusive against the hypothesis of seleniurated hydrogen, allotropic oxygen, or any other gas being the cause. Nor can it be any molecular matter driven through the air, arising from some unknown telluric source, for this would be equally diluted and dispersed. The agent evidently cannot own one single and primary origin; it may, indeed, issue from one spot, but all the phenomena of its spread show that it must, in its transit, reproduce itself. Otherwise, if a gas, it must be rendered innocuous by dilution; or, if an organic matter, by oxidation; if a suspended mineral matter, by subsidence. It must increase, and if the subject is gone into, the more fully will the idea gain upon the mind that there must be a continual reproduction of the agent to a greater or less extent in different places."

Dr. Parkes then discusses the probable origin of influenza to a fungoid source, and to contagion. Both views he feels to be full of difficulty, and concludes that it is at present impossible to come to any conclusion as to the nature of the cause.

Mr. Law, in his able article on the influenza in horses in America, strongly advocates the contagious theory. He says—"The existence of a contagion being acknowledged, can we reach any definite conclusion as to its nature? Not in the present state of science." And then he enters into the theory of Beale, and says—"The theory which sustains the virulent nature of this bioplasm is that which at present accords best with the facts observed. It explains how microscopic masses of organic matter (granules), without any regular form, size, or structure, may float
in the atmosphere indistinguishable from other inert granular matter, and yet, on gaining access to the body of a susceptible animal, may grow and increase at the expense of the native elements of such body, inducing some form of specific disease."

This hypothesis is strongly corroborated by the fact that influenza is sometimes conveyed to a healthy locality by horses affected by, or recovering from it. It is, however, negatived by its being incapable of propagation by inoculation from one horse to another; or by transfusion of blood from a diseased to a healthy horse; by its undoubted spontaneous appearance in localities in which contagion is entirely out of the question; and by its occasional occurrence when influenza prevails in man, dogs, cats, and even birds.

The influence which predisposes to influenza may be said to dwell in our large horse establishments, for scarcely a fresh horse is introduced to them without such an one, in a longer or shorter period, becoming affected with some form of the disease. May we then conclude that animal malaria, or those emanations which arise from many animals congregated together, from excretions and decomposing animal matters, give rise to sporadic or enzootic instances of the disease, and that this influence, owing to some undetermined condition of the atmosphere, may so extend as to embrace the horses of a town, a country, or a continent, and thus become epizootic or panzootic?

_Predisposing causes._—Animals crowded together in damp, ill-ventilated, and otherwise unhealthy situations, are generally the first to suffer from influenza. In them it commits its greatest havoc. Young horses are more predisposed than those of maturer years; still, the old suffer severely, and are often carried away. Sex has no influence. Neglect of every description, as well as bad food and over-work, by debilitating, render animals subject to severe and early attacks of disease. But no amount of care will exempt them from it, as it appears in the stable of the nobleman as well as that of the poorest carter. The latter, however, experiences it in its greatest intensity, and at a much earlier period than the former.

**PATHOLOGY.**

The morbid material absorbed into the blood gives rise to febrile disturbance and depression of the nervous centres. The
period of latency, between the reception of the poison and the first manifestation of symptoms, is short but uncertain. To the febrile symptoms succeed those of the specific effect of the poison upon the mucous membrane of the nose, eyes, throat, and respiratory track, as well as the intestinal mucous membrane and its ramifications in the biliary tubes. In some cases, the genito-urinary mucous membrane may participate in the inflammation, and in the majority there is more or less sympathetic or actual irritation of all the mucous membranes of the animal body.

In the majority of instances the fever precedes the catarrhal symptoms; the rigors, increased frequency of pulse, and elevation of temperature to 103° or 104° Fahrenheit, being observable prior to the appearance of any localization of the disorder. In other instances the irritation of the mucous membrane has been the first appreciable sign.

In uncomplicated cases the fever begins to abate in from three to five days, leaving the animal weak and prostrate.

It cannot be said that the fever terminates in a critical discharge, as in the human being. All that can be observed is that, coincident with the abatement of the fever, the secretions of the body become natural or slightly increased; the critical sweat, diuresis, or diarrhoea so generally observed in the human being, are usually absent in the horse.

Complications.—The catarrhal form is the one to be regarded as the simple or uncomplicated; to this is added, in some instances, pulmonic, gastric, hepatic, or rheumatic complications, peri or endocarditis, the formation of thrombi, and nervous symptoms, as convulsive fits and coma.

Symptoms of the catarrhal form.—Actual rigor may or may not precede the other symptoms; very possibly the rigor is not observed. There is a dry, staring coat, the legs, ears, and nose are cold, with redness and dryness of the Schneiderian membrane, and an elevation of temperature to 103° or 104° F. There is sneezing, a hacking cough, and shortly a defluxion, from one or both nostrils, of at first a thin, more or less acrid mucus. The eyes are heavy, conjunctivæ injected and sometimes yellow, and tears flow over the face. The symptoms increase in intensity or two or even three days. The discharge from the nose becomes flashy and more profuse. In some cases the conjunctiva of one or both eyes is actually inflamed, as marked by opacity
and imperfect vision or actual blindness. The animal heat may rise to 104° or 105° F. The cough now becomes deep, sonorous, painful, and paroxysmal, convulsing the whole body, occasioning impatience, stamping of the feet, and great distress. The temperature of the surface of the body and extremities is very variable, sometimes high, sometimes low, or one leg hot, three legs cold, and vice versa. The pulse is feeble and easily compressed, numbering generally from sixty to eighty beats per minute. The mouth is hot and clammy, and the desire for water is intensified. The head is generally depressed. The animal is made to move with difficulty, and when compelled, he does so in an unsteady manner, swaying from side to side as if partially paralyzed. This muscular debility is much increased where there is great soreness of the throat and inability to swallow food or drink.

Soreness of the throat is indicated by "quidding of the food" (that is to say, the food is chewed and ejected from the mouth), or by its return through the nostrils. In the latter case an attempt to swallow excites a violent fit of coughing, and the food imprisoned behind the velum pendulum palati is forced into the nasal chambers. It there tinges the mucus discharges with its own colour; and when the horse is fed on grass the nasal discharge is thus turned green—a cause of great fear to some people, who at once conclude that the green discharge indicates something mysterious.

The conditions of the secretions.—In the earlier stages the feces are dry, hard, pelletty, and often covered with mucus; the urine high-coloured and scanty, sometimes tinged with bile, sometimes opaque, and sometimes of the consistence and appearance of linseed oil, containing albumen, or loaded with urea and hippuric acid.

In a period of time varying from three to five days the symptoms begin to abate in intensity. The discharge from the nose becomes thick, yellow, and profuse; the cough looser, moist, and not so paroxysmal; the pulse gradually falls in number and improves in tone; the action of the heart is less jerky; the appetite improves; the throat can now be handled without causing the animal to cough. Any swelling of the throat which might have been present gradually subsides, and strength is generally restored in from twelve to fifteen days.
INFLUENZA.

The leading character of the disease consists of an inflammation of the naso-pharyngeal mucous membrane; it also gives to the secretory organs a tendency to participate in the disease. Thus it is not at all uncommon for the submaxillary and parotid glands to become inflamed, swollen, and even to suppurate. When the critical stage has passed, the debility is generally very extreme, and the loss of flesh most marked. Indeed, it is a common observation that a horse in which the fever has abated and convalescence commenced, "looks as if the flesh has melted off his bones."

Owing to the debility of the circulation, dropsical swellings appear on the belly, legs, and chest. These, however, are not to be regarded in any way as serious, for as the animal regains its strength they will rapidly disappear.

In many instances, more especially in those which have been neglected or maltreated in the earlier stages, bronchitis is apt to supervene, and its accession is indicated by the cough becoming more paroxysmal, and the difficulty of breathing (dyspnea) at first quite disproportionate to the other physical signs; the flanks heave, and the nostrils are widely dilated; in many instances the horse is said to fight for breath. The pulse, at first perhaps no quicker than the respiratory movements, which may be as frequent as 60 or 70 per minute, becomes very rapid—90, 100, or more beats per minute.

The auscultatory sounds are, roughness of the inspiratory murmur, best heard at the lower part of the trachea, and immediately behind the scapula, or the sibilant rale heard over the greater part of the chest. The first indicates bronchitis, involving the larger bronchi, the second inflammation of the smaller tubes.

The visible mucous membranes become livid, dark purple, or leaden in colour, the animal is semi-torpid from the action of non-oxidized blood on the brain and medulla oblongata. The discharge from the nose differs from that seen in the uncomplicated form, being scanty, and sometimes streaked with blood, whilst in other cases dark-coloured blood, extravasated from the engorged bronchial blood-vessels, will issue from the nostrils.

The pulse now falters, cold sweats appear on the body, and the animal sinks on the sixth, seventh, or eighth day.

The bronchitis of influenza is distinguished from other chest affections by the greater difficulty of breathing, by the respiratory
movements being relatively more disturbed than the action of the heart, by the lividity of the mucous membranes, and by the semi-comatose condition of the affected animal.

The pneumonia of influenza is characterised by a soft, dull cough, by rapidity of the pulse, great coldness of the extremities and surface of the body, by crepitation on auscultation, and dulness on percussion of the lower parts of the chest.

The inflammation of the lung tissue in influenza is characterised more by a serous than a plastic exudation—true hepatization being generally absent—mostly confined to the lower portions of the lungs. In consequence of the asthenic nature of the inflammation there is a tendency to gangrene and disintegration of the lung tissue. This termination—a rare one it must be admitted—is expressed by foetor of the breath, sweats over the body, a failing and excessively feeble pulse, rapid emaciation, looseness of the hair of the mane and tail, rapid sinking, and death.

Panzootic catarrhal fever is not very frequently complicated with pleuritis, although, during some seasons, the latter disease rages as an epizootic.

Abdominal or enteric complications.—In all catarrhal affections there is great irritability of the gastro-enteric mucous membrane, hence all teachers of experience warn their students to be careful in administering purgatives. Succeeding to the naso-laryngeal symptoms, those of abdominal pain will become manifest, the animal frequently looking at its flanks, alternately lying down and rising, kicking at its belly, and frequently passing small quantities of hardened feces, thickly coated and mixed with mucus. There is great debility, and some degree of torpor or somnolence; in some instances the sphincter ani is relaxed, and the anus constantly open, the animal straining incessantly, and exposing the intestinal mucous membrane of a deep red colour. The conjunctivae are yellow; the tongue is coated, dry, and shrunk; the animal is thirsty, and the urine is high-coloured and scanty.

Towards the termination of influenza rheumatic complications often appear; in some instances pain and stiffness in the joints appear early in the catarrhal form. Generally, however, rheumatism manifests itself towards the termination of the other symptoms. The animal becomes at first restless and uneasy, lifting its feet alternately from the ground; the joints emit a
crackling sound when moved, then swell, after which the pain subsides. In other instances the rheumatic inflammation appears in some particular muscle, or more frequently tendon, especially the great flexors of the feet. The swelling and inflammation are generally situated immediately below the knee or hock, involving the flexors—performans and perforatus. The swelling is very great, hot, painful, hard, and causing severe lameness, which sometimes remains for a long time after the animal has regained its health in other respects.

Few horses suffer from more than one attack during one season; many cases relapse, but one attack in no degree protects against another at some future period.

Prognosis.—If properly treated influenza is rarely fatal; the old, bad constitutioned, and over-worked horses only succumbing.

TREATMENT.

The practitioner is always to bear in mind that influenza is a disease which runs a definite course, and that it is in no way cut short by any interference. The treatment must consequently be directed to relieve any distressing symptom, to allay irritability, and to support the strength.

Comfortable clothing to the body and extremities; food, consisting of warm mashes of bran, boiled oats, linseed, or barley, and an abundance of good cold water for the animal to drink, are always to be recommended. It is good practice to see that the water is so placed that the animal can get at it at its pleasure, for in many instances, if it is not thirsty, it will wash its mouth and cool its tongue, and feel grateful for the relief thus afforded. Inhalations of warm water vapour, continued for an hour at a time, afford much relief, frequently mature the nasal discharges, and relieve the cough. The throat may be fomented with hot water and stimulated with an embrocation consisting of ammonia and oil, or at once blistered with the cantharides ointment. Mustard applications are very commonly used. I must confess that I use mustard externally as rarely as possible, for it causes very much distress, without securing any very marked abatement of the disease. If there be much prostration, doses of spirits of nitrous ether, or of the carbonate of ammonia, may be given in cold water two or three times a day; if the debility is not marked, half an ounce of the nitrate of potash dissolved in the animal’s drink or mixed with its mash. Par-
gatives are always to be avoided, and any constipation which may be present in the earlier stages of the disease is best relieved by enemas of warm water. Should diarrhoea spontaneously occur it must not be checked, at least if not excessive. Any irregularity of the bowels should be overcome more by food than by medicines. If costive, a laxative diet is to be given; if the reverse, it may be advisable to give dry food.

If the appetite does not return in the course of the third or fourth day, milk should be substituted for water, and if the animal likes it, it should be allowed to drink of it abundantly—say three or four gallons per day. Skimmed milk suits better than unskimmed, as the latter is apt to induce some degree of diarrhoea. If at any time the milk disagrees, and it will sometimes do so, it must be discontinued and gruel substituted. Neither milk nor gruel should be forced upon the animal by horning or bottling it down its throat in spite of its mute and often determined resistance; and it is a point worthy of remembrance that food thus forced is only calculated to disorder the digestive organs, and destroy all chance of a return of appetite. In the human being, dog, &c., food thus forced would be vomited, the stomach would at once be able to express its rebellion, but in the horse vomition rarely occurs; and who knows what unpleasantness or even pain is inflicted by thus disordered digestion, by the common, but to my mind barbarous, practice of forcing sundry quarts of gruel, beer, &c., upon its unwilling stomach.

In mild attacks of influenza but little medical treatment is necessary; pure air, comfortable loose box, without draughts, well-drained and well-ventilated, with careful nursing and careful daily medical inspection, and the saline medicine above recommended, are all that is necessary. When convalescence has commenced, the restoration is materially assisted by a few doses of, first, vegetable, and, secondly, mineral tonics, good food, carefully regulated exercise, and careful grooming. If any cough remain, it may be necessary to apply a blister to the throat, and to administer such remedies as belladonna extract and camphor; and should the swelling of the limbs continue, the kidneys are to be stimulated by diuretics.

In some rare instances the local inflammation of the larynx is very great, and the tumefaction of the mucous membrane, vocal chords, &c., interferes with the act of respiration. When this
occurs the horse’s nose is “poked out,” that is to say, the face is elevated, and the respiratory passages placed as nearly in a straight line as possible; the eyes become prominent, the inspiratory movement is performed with great difficulty, and accompanied by a loud, roaring sound. No time should be lost in giving relief to an animal in this state, and if hot fomentations and steaming fail to give relief, tracheotomy must be performed.—(See Principles and Practice of Veterinary Surgery, page 46.)

Influenza is also occasionally complicated with disorder of the liver, in which case the mucous membranes are more or less tinged with yellow; the bowels are constipated, or irregularly relaxed and torpid, the faeces are of a dirty clay colour, and fetid; the urine is high-coloured; the appetite is almost lost; and in some instances there are convulsive fits and comatose periods, which cause much alarm. Professor Dick was of opinion that these cerebral symptoms were due to the extension of the nasal inflammation to the meninges of the brain, through the cribiform plates of the ethmoid. They are, however, due to the presence of biliary matters and products of degeneration of tissue in the blood, and are to be overcome by elimination through the natural channels. Some practitioners have termed this “bilious fever,” but there is no necessity for any distinguishing term, as it is due to turbulence of the lining membrane of the bile ducts preventing the free flow from the liver into the duodenum of bile, which, accumulating in the liver, is absorbed into the circulation, giving the visible mucous membranes the characteristic yellow, jaundiced tinge.

I have never found it necessary to administer any liver stimulant in this complication. All that is necessary is to keep the bowels regular by a mild aperient, such as a pint of linseed oil, and allow the animal such food as it will partake of which is of an easily digested and aperient nature. One condition which often prevails in this form requires modification, as it is apt to cause some degree of suffering, namely, an acid state of the stomach. The acidity of the stomach is manifested by grinding of the teeth, licking the walls, placing the tongue on cold objects, with drivelling of a clear saliva from the mouth. The bicarbonate of soda is very useful, giving speedy relief from this annoying symptom. The medicine is to be given two or three times a day, either dissolved in the drinking water, or as a draught out of a bottle.
If there be abdominal complications, the colicky pains are to be relieved by warm fomentations to the belly, and small doses of opium, the bowels being regulated by oil. But even here no very decided and heroic steps are to be taken to relieve symptoms, it being always kept in view that they are the result of a cause which will not expend itself until a certain period, and that mere remedies, although perhaps affording relief at the time, are generally debilitating in their effects, and often tend to cause a fatal termination.

The sequelæ of influenza are, hydrops pericardii, hydrothorax, ulceration of the larynx, roaring, and sometimes glanders and farcy.

MOBILD ANATOMY.

Uncomplicated influenza seldom proves fatal, except in the very old or otherwise debilitated animal; the most prominent lesions being great congestion of the mucous membrane of the respiratory track, extending even into the minute bronchi, some of which are filled with a muco-purulent discharge; the pulmonary lobules being consequently collapsed. The blood is dark, and is said to contain micrococci. The majority of fatal terminations are caused by the gravity of some local complication, such as pneumonia, bronchitis, &c.

Fig. 14.—Congestive patch on mucous membrane of stomach.
(Specimen sent by Mr. T. Taylor, V.S., Manchester.)

In Manchester it has been found that many dead animals present a dark patch of congestion, with incipient ulceration on the mucous membrane of the stomach, as shown above.
CHAPTER XXIX.

ENZOOTIC AND EPIZOOTIC DISEASES—continued.

MALIGNANT CATARRHAL FEVER OF THE OX.

A malignant form of catarrhal fever, sometimes, but erroneously, called glanders of the ox tribe, due to the operation of a morbid poison, which expends its specific effects upon the mucous membrane lining the sinuses of the head and nasal chambers; manifested by rigors, dulness, and debility, succeeded by the mucous membranes becoming of a bluish-red colour, the eyes closed, the eyelids swollen, and flowing of tears over the cheeks. There is a painful and frequent cough; the pulse is feeble; bowels costive at first, but diarrhoea soon succeeds. In the course of a few hours after the onset of the disease, a profuse discharge issues from the nostrils, mouth, and eyes; the sinuses of the face and head become filled with purulent matter, and in some instances the horns drop off.

The connection between the bone of the horn (flints) and the sinuses of the head is very intimate, for the bony process, the horn core, which springs from the crest of the frontal bone is hollow, and this hollow is continuous with the frontal sinus. This hollow or sinus in the horn-process is very vascular, and its blood-vessels anastomose with those upon its periosteal surface. Any influence, then, which causes inflammatory action in the sinuses, easily induces the same processes in those structures which are so intimately connected; and such we find it to be the case in malignant catarrhal fever,—inflammation is excited in the sinuses of the flint, which extends to the surface of the bones, and the consequent suppuration detaches the horny coverings.

The symptoms of this affection are not dissimilar to those
of cattle plague, but it does not, like the latter, spread by contagion; indeed, it is a non-contagious disease, the result of exposure to cold. The discharge from the nostrils is more profuse than in the plague, purulent or sanguino-purulent, and the horns fall off.

There may be appearances on the mouth and in the visible mucous membranes very similar to those of rinderpest; and in some instances lameness and sloughing of the hoofs may lead one to suppose that it is an aggravated form of contagious eczema.

TREATMENT.

Removal to warm, sheltered sheds; enemas, to relieve constipation; stimulants, such as the carbonate or acetate of ammonia and the spirits of nitrous ether, with hot water vapour to the nostrils, constitute the treatment of the earlier stages. If the animal survive, these remedies may be succeeded by tonics, mineral acids, and good food. The disease is very fatal, and causes death in from three to seven days. If the animal live over the latter period convalescence may be expected. Violent remedies, such as strong doses of salts, bleeding, calomel, &c., always hasten the fatal termination. If aperients are imperatively called for, oil or treacle are preferable to the more drastic agents.
CHAPTER XXX

ENZOOTIC AND EPIZOOTIC DISEASES—continued.

EPIZOOTIC CELLULITIS.

Under this term I am inclined to place a form of epizootic disease which prevails occasionally, particularly during a long continuance of cold wet weather, both in England and Scotland, variously called rheumatic influenza, muco-enteritis, pink-eye, &c.

SYMPTOMS.

The primary symptoms are those of fever, rigors, dulness, succeeded by swelling of the eyelids, discharge of tears from the eyes, pain in the limbs, and tumefaction, more particularly around the articulations.

The pain in the limbs is manifested by restlessness, shifting of the feet, and irritability; the succeeding swellings are superficial, involving the subcutaneous areolar tissue, and their occurrence gives relief to the pain. At first they are limited, but soon extend upwards and downwards, embracing the greater extent of the limb or limbs affected. The pulse is hard in this disease, and the impulse strong, the temperature of the body elevated to 103° or 104°; and when blood is withdrawn it coagulates firmly, and manifests the presence of an increased quantity of fibrin. The condition of the intestinal canal is disordered; there is constipation, the fæces generally covered with much mucus, and their colour frequently indicates the absence of biliary secretion, or the presence of altered bile,—being tinged or stained with coffee-coloured streaks; the rectum is irritable, and the passage of fæces causes some degree of pain; hence the term muco-enteritis.

The colour of the conjunctivæ is altered to a pink; hence the term "pink-eye." There is often a loud cough, at first dry, but often becoming moist, but there are no signs of serious pulmonary complications.

The disease runs its course and terminates favourably in from
four to six days, leaving the animal but little altered. There is not
the debility of influenza, nor is the recovery so prolonged as when
an animal has suffered from inflammation of an important organ.
In some instances the pulse, at first strong, becomes gradually
feeble, the horse the while presenting no other bad symptom,
the pain having left the limbs, the appetite returning, the swell-
ings diminishing, and the secretions having regained their normal
condition. Several instances of this kind have come under my
observation, and whilst all but the careful veterinary observer
have been confident of a rapid recovery, the horse has suddenly
died, the post mortem examination revealing the presence of
thrombi in the cavities of the heart, the heart itself and its
membranes showing no trace of disease. In other instances
recovery has taken place, and the animal has been sent to its
work, continuing well for weeks or months, when in some cases
death has occurred from rupture and degeneration of the liver;
whilst in others, signs of cerebral disturbance have become
evident, the patients eventually dying from coma and general
paralysis.

The post mortem examination of all these instances has brought
to light that there has been plugging of the blood-vessels of
supply—the hepatic and cerebral arteries.

Now, if we inquire how this has been brought about, we shall
find that in the first place the disease is one attacking the
areolar tissue; and inflammation of connective tissue, like that
of the more truly fibrous, causes the development of the fibrin-
ous crisis; the coagulating properties of the blood are thus
increased, and, owing perhaps to some local but undeniable
fault in the blood-vessels or heart, coagulation has
taken place in the living body, ultimately leading to a fatal
termination.

It is necessary to bear this in mind, in order to overcome
this fatal tendency, and such medicaments as have the property
of preventing this liability to coagulation are to be administered.

TREATMENT.

By carefully watching this disease it will be observed that
spontaneous diarrhoea sometimes occurs, which immediately
relieves the symptoms. In some cases looseness of the bowels
occurs on the second day, to the manifest relief of the animal.
But all cases do not terminate thus; and in order to bring this favourable issue about, nature has to be copied, and a mild cathartic, say four drachms of aloes, administered in the earliest stages. This treatment seldom fails to give relief, more particularly if it be supplemented by warm fomentations, succeeded by bandages, to the affected extremities. After the aperient has ceased to operate, the horse is to have moderate doses of the nitrate of potash in its drinking water. The supply of food must at first be spare, and of a cooling nature; bran mashes and a little hay will be quite sufficient.

If, however, the patient is not seen for two or three days after attack, more particularly if it has been irrationally treated or kept at work, if there be debility, feebleness of the pulse, and increased respiratory movements, and if there be a probability of a fatal termination by the formation of clots in the cardiac ventricles, the treatment must be more energetic. It is believed that two things are necessary for the rapid production of cardiac clots, namely, debility of the organ (the heart), and a coagulative tendency in the blood.

Both of these conditions must then be combated, the first by stimulants, and the latter by salines, which diminish coagulability. Both of these properties are possessed, to some extent, by ammonia, and hence the administration of the ammonia carbonate is to be recommended; for the same purpose the nitrate of potash, combined with stimulants, is also very useful. The nitrate of potash may be given in large doses, if sufficiently diluted, and the best method of procedure is to dissolve two ounces in half a bucketful of cold water, and allow the animal to drink it. This quantity may be given twice in the twenty-four hours, and in smaller doses for two or three succeeding days. In addition to its effect on the blood, it stimulates the kidneys to greater action, and thus causes increased elimination of effete materials.

The heart's action must be carefully noted in these doubtful cases, and stimulants administered whenever the pulse begins to falter. The administration of purgatives in the later stages must receive due consideration; if there be debility, aloes must on no account be given, as it tends to depress the heart's action; and a relaxed state of the faeces must be obtained by perhaps a dose of oil or laxative food; treacle in bran mash is a good laxative.
CHAPTER XXXI.

ENZOOTIC AND EPIZOOTIC DISEASES—continued.

EPIZOOTIC PLEURITIS AND PLEURO-PNEUMONIA OF THE HORSE.

Definition.—An inflammation of the pleura and substance of the lungs, preceded and accompanied by a low typhoid or adynamic form of fever, which lasts from seven to fourteen days. It generally occurs but once in a season, but one attack does not render an animal exempt from a second or third.

For the last few years this form of influenza has prevailed to a very great extent both in the north and south of Britain. Erroneously called "influenza," it has seemingly and for some time taken the place of that affection, from which it differs very materially. The true uncomplicated influenza is a disease of the mucous structures: this affects the serous covering and substance of the lungs.

In 1861-2 this form of epizootic disease became very prevalent in the north of England, where it raged for many months, committing great havoc amongst horses of all kinds, but particularly amongst those most exposed to the vicissitudes of the climate. It has prevailed more or less ever since, both in town and country, more particularly amongst young horses and those removed from pastures into stables. The knowledge that nearly every newly purchased horse is liable to suffer from this or some other form of epizootic disease, deters many persons from keeping horses, and hence we find that many whose business requires that horses should be employed, prefer to let out their work to contractors and carriers. This repugnance to purchase and keep horses by men in business has also been increased by the great mortality which has generally resulted from this epizootic.
ETIOLOGY.

Alternations of heat and cold are undoubtedly the most prolific causes, for the disease prevails mostly in the spring and early summer months, when the winds are cold, and the heat of the sun more or less powerful. Animals at this time are more predisposed to disease than at any other season of the year; their skins being in a delicate condition, consequent upon the process of moulting, and the heat of the sun, acting upon the skin when in this condition, causes some degree of hypersensitivity. When the sky becomes clouded and the rays of the sun are excluded, more particularly if a cold wind is blowing, some degree of rigor or shivering is caused, the hair stands on end—"pen-feathered"—the horse draws its legs together, and if kept standing, perhaps waiting for its load, for but a short time, it is apt to become subject to an attack of pleurisy.

It is very generally believed that this, as well as all other epizootic diseases, is contagious and infectious, and during some outbreaks this seems to be the case, whilst in others it is out of the question. This incongruity seems to depend upon the virulence of the disease. When the character of the outbreak is mild the disease seems to be non-contagious; when violent or acute, it presents such marked signs of being contagious, that even the most sceptical is forced to believe in this method of propagation. This peculiarity in the character of the disease can only be accounted for by the facts brought to light by Dr. Lionel Beale, who says that "in cases where the body heat rises several degrees in the course of a few hours the germinal matter increases with great rapidity. The capillaries of a great part of the body are found to be gorged with particles of living matter, for the most part descended from the colourless blood corpuscles, while the masses of bioplasm of the neighbouring tissues have increased to twice their normal size." If this be true, and there is no reason to doubt its correctness, and if it be a fact that particles of living matter escaped from the body of one animal are capable of reproducing themselves, and during that process cause similar pathological changes in the body of another animal to which they have gained access, we can understand how a disease, when virulent, may become contagious, that when mild may not be so. This conclusion is borne out by what is observed
in enteric fever in man, which at times has an infectiousness
which on other occasions is wanting.

Having the probability of the spread of pleuritis by contagion
in view, it will be well for the practitioner to take all precautions
against its propagation by this cause.

**SEMIOLGY.**

The primary symptoms are very often more or less obscure.
The animal is dull, dejected, off its food, performs ordinary
labour with difficulty; lassitude, perspiration, and fatigue are
easily induced. Examined carefully, the pulse will number from
sixty up to eighty per minute—during some seasons eighty has
been the common number—and the animal temperature will vary
from 103° to 104°. Sometimes there is a cough from the com-
 mencement; very often, however, there is no cough during the
first three or four days. The extremities and ears are alternately
hot and cold; the appetite is almost entirely lost; the alvine
and urinary secretions are defective; the visible mucous mem-
brane injected, and frequently of a rusty tinge; in some cases
there is a rash in the mouth, the tongue is generally foul, and
the abdomen is "tucked up." The animal does not lie down.
Auscultation does not reveal much at first; in fact, for three
or four days the animal may be said to be suffering from
fever without local complications, but at the end of that period
a hard, dry, painful cough is now and then heard; the thoracic
walls are fixed; the breathing is abdominal; the elbows are
turned out, and a line or hollow extends from the ensiform car-
tilage of the sternum to the anterior spine of the ileum, which
denotes that the ribs are fixed, owing to pain within the chest.
If the horse is now made to move suddenly, it emits a grunt or
groan; in some instances it groans at each expiration, and if
slightly rapped in the chest with the knuckles it will do so
with pain; the breathing is catching and short, and auscultation
will detect a friction sound.—(See Pleurisy.) Very commonly
the right side only is affected, in some cases the left, and in rare
instances both sides.

In the course of the next ensuing two days, the sounds of
the chest indicate pleurisy, pleuro-pneumonia, or a complica-
tion of these with pericarditis. From the commencement of the
manifestation of chest disease, the breathing becomes somewhat hurried, the pulse assuming a hardness of character which it did not possess at first; the number of its beats are not further increased; on the contrary, rapidity of the pulse may decrease as the exudation on the pleural surfaces advances, and it is not at all uncommon for one to witness an increased rapidity of the respiratory movements, gradual condensation of lung tissue, some effusion into the thoracic cavity, and a diminution in the number of the pulsations. If pericardiac complications are present the pulse is marked by a peculiar indistinctiveness and irregularity; the cardiac beat is generally loud and short; the impulse, however, is weak, and the arterial pulsations indistinct.

In some instances the whole body becomes stiff and sore, and the horse is disinclined to move, but stands with its nose extended forwards, nostrils dilated, and fore legs apart, presenting an appearance of distress, which is heightened by frequent looks at its sides, and by attempts to lie down, as if suffering from colicky pains. In such instances the respiratory movements are short, shallow, and much accelerated, numbering fifty, sixty, or even eighty or more per minute, whereas in the majority of cases they do not number more than thirty per minute, when auscultation may detect considerable exudation into the lung tissue.

An examination of the respiratory apparatus by percussion and auscultation—the only satisfactory method of diagnosing chest diseases—will enable the practitioner to detect the various changes as they occur.

1. For the first two or three days after attack both percussion and auscultation often give negative results; at the termination of that period percussion over the seat of the pleural inflammation will cause the animal to groan. Auscultation will detect a dry friction sound if the pleura be affected; absence of true respiratory murmur, and the presence of crepitations, large or small, if the lung-substance be involved; a combination of friction sound, and crepitations, if both pleura and lung tissue, and a "to-and-fro" rasping friction sound, with more or less palpitation, if the pericardium be involved.

These signs indicate—1st. That the natural pleural secretion is arrested, and that the dry pleural surfaces rubbing on each
other cause the friction sound; 2d. That engorgement of the lung tissue has taken place; and 3d. That the pericardial secretion is arrested, causing the "to-and-fro" sound at the heart.

2. In the course of from one to two days the above abnormal sounds disappear. Auscultation now reveals that in the part affected there is no sound at all, or that a tubular or hollow sound is heard. The absence of sound indicates either that the lung tissue has become impervious to air, or that a considerable effusion of serum has occurred into the thoracic cavity. If the former, the absence of sound becomes apparent by degrees only; that is to say, the respiratory sounds become gradually feeble as the consolidated part is approached, showing that at the border of the hepatized tissue the inflammatory process is less advanced. There may be crepitations or tubal sounds, but when the absence of sound is due to effusion of serum (hydrothorax) the sounds terminate abruptly at a certain distance from the floor of the thorax, the respiratory sounds being louder than natural above the line of termination, and in some instances the presence of fluid in the chest will be indicated by a "dripping sound," as of drops of water falling into a well. The tubal sounds indicate a less degree of consolidation; that air finds ingress into some of the bronchial tubes, but not into the more minute ones and air cells.

This condition may exist for three or more days, and then the crepitations reappear, showing that the exudate is breaking up and becoming gradually removed by absorption; the dull impervious part at the floor of the cavity becoming daily shallower, and the normal sounds slowly returning.

Percussion during the stages of consolidation and effusion produces a dull sound over the diseased part, and increased resonance over the healthy parts of the chest. In all the unaffected portions of the lungs the respiratory murmur is increased.

The "to-and-fro" cardiac friction sound also disappears, owing to effusion into the pericardial sac, and reappears as the exudate is removed by absorption.

Very often after convalescence has been established the cough becomes more frequent; it, however, loses its painful hacking character, being now louder and stronger. In some instances, more especially if the exudate has been very abundant, a mal-
condition of the system is induced by the abundance of effete materials in the circulation, removed by absorption from the transformed exudates. This has been compared by Professor Gungee to the hectic fever of the human being. There is much emaciation, imperfect digestion, capriciousness of the appetite; the hair is easily removed from the mane and tail; irregularity in the surface temperature; and continuance of the increased temperature of the body, as indicated by the thermometer. If this condition of the system be not successfully combated, the respirations again become accelerated and the ribs fixed; there is flapping of the nostrils, which are greatly distended; the animal again discontinues to lie down. Anasarcaous swellings may appear on the chest, abdomen, and the legs, denoting the presence of hydrothorax, to which the animal may eventually succumb in the course of an indefinite period—sometimes in two or three days only, sometimes in as many weeks—or symptoms of farcy or glands may appear.

**POST MORTEM APPEARANCES.**

In very acute cases, the appearances revealed by a *post mortem* examination are, intense redness of the pleural surfaces of one or both sides of the chest; the engorgement of the vessels embracing the visceral and parietal surfaces, and some degree of effusion and exudation of lymph. In some instances, the lungs show but little disease, whilst in others patches of inflammation are found throughout their substance. The pericardium and endocardium are generally more or less injected, and the death of the animal at this early stage generally results more from the cardiac complication than the pleural disease. It is but seldom that a case terminates so rapidly, unless the animal be kept at work after it has fallen ill.

If the horse live for two or three days after the pleural symptoms have become manifested, along with the injection of the vessels, an abundant quantity of serum will be effused into the pleural sac, floating in which, and loosely adherent to the pleural surfaces, bands of lymph will be found. These bands of lymph are loose and watery, and the serum is turbid or flocculent. If the horse has lain for some hours after death, and the *post*
mortem is carefully performed, the effusion is clear at its upper
and turbid at its lower part.

If the inflammatory process has been less rapid, the lymph is
of a more consistent appearance, and forms over the inflamed
parts flocculi of various sizes, or a distinct lining varying in
thickness, and of a honey-combed appearance; but the lymph in
the epizootic form does not possess the firmness, plasticity, and
tendency to organization which is characteristic of that of the
sporadic form of the disease. These bands of lymph are some-
times of very rapid formation, and they may even show some
trace of organization in forty-eight hours after attack. This fact
is of considerable importance legally, as it is often found that
if a horse dies in a week or two after purchase, an attempt is
made to compel the seller to refund the purchase-money on the
ground that the animal was diseased prior to the date of sale.
Old bands of lymph, and such as indicate previous disease, are
firm, organized, of a glistening appearance, and unite the oppos-
ing surfaces more or less firmly together. New bands of lymph,
on the contrary, are soft, watery, and the parts which they may
attach together are easily separated.

In some instances, extravasations of blood give the lymph a
red colour. This must not be mistaken for vascularity, as the
latter would denote organization and age.

Examined microscopically, the lymph exhibits the presence
of numerous inflammatory corpuscles, oil globules, and ill-
developed fibres.

The exudate into the lung tissue is also wanting in plasticity,
the lung cuts up soft and moist, a whitish fluid oozing from the
cut surfaces.

In some cases, where the vital powers have been very low, or
where they have become weakened by injudicious treatment, an
abundant, turbid, fetid fluid has been thrown out, partaking
much of the character of unhealthy pus; or abscesses form in
the lungs, and in rare instances gangrene of the lungs has
occurred.

The pulmonary complication is generally found at the inferior
portions of the lung, and in many instances the exudate indi-
cates that the process is wanting in the true character of plastic
inflammation.
EPIZOOTIC PLEURISY.

TREATMENT.

From the foregoing observations, it will be understood that the local complications of this disease are preceded by fever, the pleural and pulmonary inflammation appearing after a few days have elapsed. The fever is of a typhoid or adynamic character, and the severity of the chest affection is generally in accordance with that of the premonitory fever. The fever, slight perhaps at first, is very often intensified by the suffering animal being kept at its ordinary work for some time after the appetite has failed. This inattention on the part of those in charge of horses is often a cause of great loss, inducing a fatal termination where recovery might reasonably have been expected. The febrile state and the local inflammation are increased by all debilitating influences, such as bad food, previous disease, natural delicacy of constitution, by the abstraction of blood, and very commonly by the administration of purgatives. Many horses are destroyed by the administration of aloe, a dose of which is often given when the horse is seen to be “off his feed.” Superpurgation may not be induced, but the chest inflammation is much increased, and the animal often succumbs.

There is another practice in vogue, more particularly amongst horse-dealers, namely, that of giving a purgative (aloetic) ball to nearly every fresh horse they buy, and this is done without taking the health of the animal at the time into consideration at all. I am convinced that this is a most reprehensible practice, leading to grave pulmonary diseases and to death, more especially if an epizootic is prevalent.

The pathology of chest inflammation leads us to the conclusion that when once established it runs through certain stages, namely, congestion of the vessels, the outpouring of an effusion, and the formation of an exudate. The congestion, effusion, and exudation are determined by the intensity of the preceding fever. If the fever is slight, the local disease will be slight also; if, on the contrary, the fever is severe, the local inflammation will be proportionately grave. During some seasons the disease from its commencement is severe, and then the weakly succumb. But at other times this is not the case, and very few deaths result from the disease; but its character is always rendered more serious by irrational treatment.
The duration of the fever cannot be cut short by any treatment, and attempts to do this are very often the cause of numerous deaths. Its severity, however, is amenable to modification by—
(1.) Complete rest whenever the slightest sign of illness is discoverable.
(2.) By housing the animal in a warm, dry, light, well-ventilated loose box.
(3.) By taking special precautions that no draught of cold wind blows upon it; for it must be remembered that cold, more especially cold wind, is the common cause of the disease, and that removal of the cause is the first step in the treatment of all diseases; and, again, that the severity of many affections is dependent on the "dose" of the cause. When this is heavy or long continued, the results will also be heavy and severe.
(4.) By clothing the animal and bandaging the legs, in fact by keeping up the equilibrium of the circulation; for if the vessels of the skin are prevented, by the operation of cold—acting upon and constringing them—from receiving a due supply of blood, internal congestions and inflammations are aggravated and often determined.

In addition to these rules, the practitioner must remember that the disease, once established, is the effect of a cause which has been in operation for some time past; that the effects, whatever they may be, are the natural physiological responses of the animal body to the action of such cause or causes; and that all attempts to remove such effects or conditions by other than those processes which nature herself attempts, and generally accomplishes, can only result in disappointment and loss.

How, then, does the animal body rid itself of disease and its results? Briefly, in the one before us, the inflammation is the result of an irritant, acting for a certain time upon a certain tissue or organ. If the dose of the irritant is strong, the resulting inflammation will be strong also, and nothing will subdue that inflammation so long as the cause retains its strength and is allowed to operate. This inflammation is characterised by congestion, effusion, and exudation. When the cause is removed, or when its strength is exhausted, the congestion slowly disappears, and the products of the inflammation, namely (1.) the effusion, is gradually taken up into the circulation and removed from the body by the excretory organs; and (2.)
the exudation or lymph, degenerated into a turbid fluid material — the pathological milk of Virchow — is removed in the same manner as the serous effusion, or becomes organized into a fibrous structure, which binds the surface of the opposing parts together, and constitutes adhesion. When this adhesion is completed, the new structure becomes a part of the living body.

Seeing, then, that the various changes are natural results of the operation of a cause, the practitioner must be careful to avoid doing anything that is calculated to irritate or debilitate the animal body. At the same time he must be careful to keep the excretory organs in a natural condition, maintain the strength by appropriate diet, and allay morbid irritability by the administration and application of suitable remedies.

In the first place, the practitioner is to avoid irritating and debilitating his patient. In order to accomplish this, three methods of treatment now pursued by many practitioners must be abandoned, namely, bleeding, purging, and counter-irritation.

Bleeding and purging, separately or conjointly, lower the animal powers, which are already too low, and prevent the physiological changes from taking place which are essential to the final removal of the disease. If they do not kill in a very short period of time, they cause an alteration in the inflammatory process, whereby large quantities of an aplanic material are formed, which, by blocking up the lung tissue, or filling the cavity of the chest, cause death by suffocation; and by their debilitating influence generally render the vital powers less able to resist even a mild attack of disease.

Counter-irritation.—This is the favourite method of treatment at the present time, and it is accomplished, or thought to be accomplished, by the application of mustard, cantharides, or other irritants to the skin of the sides and breast. It is applied on the principle that no two inflammations can exist in the body at the same time; that an artificial inflammation of the skin, excited by the irritant, removes or destroys that which is going on within the chest. Others say that it rouses the capillary circulation, removes congestion, &c.

For many years I followed this method of treatment, and so plausible were the arguments in its favour, that I could scarcely bring myself to believe that it could do harm, although I saw that many horses died even when a blister had acted. I was at
last induced to abandon it altogether, and the result has been most satisfactory.

Irritation of the sides and breast is injurious in all instances of chest disease in the horse, except in a condition presently to be described, and for the following reasons:—

1st. It cannot and does not remove the internal inflammation. Many post mortem examinations have convinced me of this. During the summer of 1873 I had a good opportunity of demonstrating this fact to my students. A horse newly bought by a dealer died from pleurisy, and its value was in dispute between buyer and seller. On viewing the carcase, both myself and students were struck with the violence of the inflammation of the skin upon the sides, induced by the repeated applications of irritants. Some of the students, having been pupils of gentlemen who advocated the "counter-irritation" theory, were under the firm belief that no internal inflammation could exist where the external was so very marked. The result, however, proved the fallacy of the hypothesis, for the pleura was intensely inflamed.

The internal inflammation being an effect, until it can be proved that an external irritant can remove the cause which has produced such effect, it is quite as reasonable to suppose that a blister on the palm will remove or prevent the effects of another on the back of the hand, as it is to think that a blister on the outside of the chest, no matter how soon applied, can remove an irritant, or prevent it from affecting the internal structures.

2nd. Another argument which tells against blisters is the fact that their advocates differ as to the stage at which they ought to be applied. One party says they cannot be applied too soon, in order to counteract the internal inflammation, "by drawing the morbid action and the blood to the surface;" whilst another says that external irritants do harm whilst there is any fever present, and that they should always be applied after the pulse has fallen and when convalescence has commenced, in order to stimulate the removal of the products of the inflammation. I, however, fail to see the necessity of doing this; for the removal of the exudates is a physiological process, best accomplished when uninterfered with, and counter-irritation at this period can only retard the recovery, or, by again setting up the febrile condition, bring about a fatal termination.
There is, however, a very rare exception to these objections to external stimulants during the second stage of the disease, occurring in that condition where the horse neither gets better nor worse for several days—"hangs fire," as it is commonly termed. In such instances a weak solution of mustard, by gently stimulating the skin, will often induce the beginning of convalescence, and act as a stimulant to the whole body. In no other condition are counter-irritants beneficial, and in this, care must be taken not to apply them too strong nor for too long a time. The sides should be quickly rubbed over with about two or three ounces of mustard mixed in a quart of warm water, and the parts covered over with paper or linen. If one application does no good, it is not advisable to apply another; but if the horse seems to improve for a time and then relapse, a second or even third application may be admissible.

3d. The application of blisters causes pain and increases the fever. If applied to the sides they impede the respiratory movements by the pain they cause, and thus add to the distress and suffering of the animal. The cantharidin absorbed into the system causes irritation of the urinary organs, sometimes congestion of the kidneys, interferes with their excretory functions, and by the pain and disturbance thus induced adds materially to the febrile condition, and often causes the animal's death. Horses that recover from the disease naturally do so much more rapidly than those which have been blistered, and which are often a long time in overcoming the effects of the blister; with raw sides, they remain for weeks in their stables unfit for work. Sometimes, more especially if the blisters have been oft repeated, the animal becomes much emaciated, is unthrifty, the blistered skin will slough, and when it finally recovers the blemish remains for life. Finally, animals which die from the disease do so much easier than those which have been severely blistered. Indeed, the agony of death from disease bears no comparison to that from treatment.

Having now pretty strongly condemned what I consider to be wrong in principle and disastrous in practice, I must proceed to describe the treatment which has proved successful.

During the premonitory fever, in addition to housing, clothing, &c., already described, the animal is to be allowed an abundant supply of cold water to drink, warm or cold bran mashes, which-
ever it likes best, to eat, a boiled linseed mash every night, roots, such as carrots, turnips, or potatoes, with a handful or two of the best and sweetest of hay, or grass if in season. If the alterations of the temperature of the skin be very marked, two or three doses of spirits of nitrous ether are to be daily administered in warm water; and to excite the action of the kidneys, which is often in abeyance, the ether is to be supplemented by half-ounce doses of the nitrate of potash. When the fever is high and the symptoms acute, great benefit will be derived from aconite, ten-minim doses of Fleming’s tincture being given in a ball two or three times a day. If the bowels are costive, clysters of warm water are to be administered, and in rare instances, where the bowels are extraordinarily torpid, a dose of linseed oil. In the majority of cases, however, laxative food will effect all that is necessary, and it is better to avoid even the oil, except where the constipation continues, or where it causes uneasiness.

The chest is to be carefully examined at least once a day, and when convenient the animal temperature registered, as well as the pulse and number of respirations.

If at the onset of the pleural inflammation there be pain and distress, manifested by the horse looking to its sides and grunting, or attempting to lie down, opium is to be given to alleviate the pain. It must be administered carefully in the form of tincture; and in order to prevent its constipating effects, from eight to twelve ounces of oil are to be given. One or two doses will be sufficient, for when the dry condition of the first stage of the inflammation has passed away, pain generally disappears. If the symptoms are those of irritation rather than pain, the aconite is to be given in preference to the opium; and at any time during the progress of the disease, if irritability is much increased, a dose or two of aconite will prove serviceable. In addition to the opium, warm, soothing—not hot, scalding—fomentations to the sides give great relief. These warm fomentations are to be applied for at least an hour three or four times a day in every severe case; and in all instances, whenever the breathing becomes catching or accelerated, they must be applied until relief is given. In many cases their effect in allaying pain and soothing the animal is most marked, the patient often giving a “sigh of relief” in a few minutes. The best method of applying them is either to wrap the horse’s body in a thick blanket.
or horse sheet, and pour warm water upon it, placing a tub so as to catch the water as it falls from the sheet, or to wring cloths out of warm water and apply them to the sides. The latter method is the cleaner, as there is less water lost on the bedding, &c.; but in the former the skin is not exposed during the fomentation, and is to be preferred. When the fomentation is concluded, the wet sheets are to be covered with a waterproof covering, or, if removed, the skin lightly rubbed with weak ammonia liniment, say one ounce of liquid ammonia to sixteen of oil, for the purpose of preventing the sensation of cold which is apt to follow warm applications.

As the local inflammation progresses the nitrate of potash is to be slightly increased. From one to two ounces may be given in the twenty-four hours, and it always acts best dissolved in the drinking water, as the horse can then sip it at its leisure. It lowers the animal heat, cleans the mouth, has some effect on the exudation, and stimulates the kidneys. When the diuresis becomes increased, the nitrate must be discontinued, and if the horse is progressing favourably, but little more is needed. In the course of a few days, if the appetite is not good, vegetable, and afterwards mineral tonics, are to be given. In many cases, where the kidneys act very languidly a few doses of colchicum will prove of great service. I think the colchicum seeds are the best, made into a tincture, and given in doses containing one to two drachms, for two or three days, or until diuresis is induced. The colchicum, in virtue of its action in causing the elimination of the solid ingredients of the urine, removes from the economy much effete material, products of the metamorphosis of the inflammatory exudates.

Some veterinarians are very fond of giving the carbonate of ammonia as a stimulant in all typhoid diseases. If the kidneys are acting freely it is a very useful stimulant, but if the secretion of urine is diminished its administration only tends to load the system with ammonia—when it is already over-burdened with the products of tissue changes, all tending to be resolved to ammonia, carbonic acid, and water; but if administered in conjunction with the vegetable tonics in the later stages, it tends to stimulate the appetite, and restore strength. It should always be given in a ball, as solutions tend to irritate the mouth, and prevent the horse from eating.
If the appetite is very much impaired, the horse must have an abundant allowance of milk to drink instead of water. Some horses are very fond of milk, and almost all will partake of it after tasting it a few times. If the debility is excessive, eggs beaten up with the milk will prove of great service. They supply those constituents which are required by the wasted tissues. If milk is refused, the animal must have gruel, linseed tea, or hay tea, but nothing in the shape of food must be forced upon it.

Of the termination of pleuro-pneumonia in hydrothorax I have only to say that since I have abandoned the heroic and counter-irritating treatment, hydrothorax has been almost unknown to me. Other terminations, such as rheumatism, roaring, thick wind, &c., will be described under their proper heads.
CHAPTER XXXII.

EPIZOOTIC AND ENZOOTIC DISEASES—continued.

EPIZOOTIC CEREBRO-SPINAL MENINGITIS.¹

Epizootic cerebro-spinal meningitis, or, more properly, cerebro-spinal fever, is a disease of which until recently comparatively little has been known. More especially is this the case in veterinary practice, and indeed I think it may be said that no veterinary writer has as yet given to it the attention which, considering its increasing frequency, it demands. Viborg, however, has observed this disease an epizootic, and Stockflett and Bagge have studied it in Denmark, where it has appeared almost annually since 1852.

The first appearance of this fever amongst horses that I am aware of in the United States, to which place all my observations of the disease are confined, was in New York during the winter and towards the spring of 1871, where it appeared with great virulence amongst the horses used by the Street Railway Companies, quickly spreading to and affecting horses of all conditions and classes, with a tremendous fatality, creating for a while great consternation amongst horse owners.

The following extracts, made from a daily paper of the time, may serve to show the formidable character of the disease. It is headed Death in the Stables, and says—"The mysterious horse disease which recently broke out here has, after a partial subsidence, again assumed terrible and fatal proportions, doing its work principally amongst the horses in the City Railway stables. On Thursday, in one stable, there were twenty-six new cases, and several horses died. In another, the live stock of the line were falling victims to the disease so rapidly that an almost entire with-

¹ By C. J. Llanes, V.S., Boston, U.S.A.
drawal of their cars became necessary. On another line a large proportion of the stock was laid up during Wednesday night and Thursday morning, and on Thursday night many of the horses were dying. In another stable more than 125 horses are disabled, and the hospital is being almost as rapidly depleted of dead horses as it is being filled with sick ones." The disease soon appeared in other places, and in Boston, nearly 300 miles distant. At about this time I saw at the stable of an omnibus company several scores of horses under treatment at the same time. These extracts are made merely to show the very formidable character of the disease when it does present itself, which luckily is seldom, although it appeared with us again during the winter following, but not to such an enormous extent as at first, and confining itself principally to well-kept horses, and the ratio of deaths was much decreased. It may be defined as being a malignant, non-contagious epizootic fever of the zymotic class, occurring during the winter and early spring months, and affecting the coverings and surface of the brain and spinal cord.

Its causes, except in so far as it confines itself to the cold months, are involved in mystery. It seems to attack all classes of horses, but evidently prefers those that are of rather the superior order, and well kept. Well or ill drained and ventilated stables apparently have no effect upon it, therefore we may say it is due to a specific poison, which, existing in the air, becomes absorbed in the system, and according to the amount so absorbed or the susceptibility of the subject, are the symptoms more or less developed. It presents itself in a variety of ways. There may be premonitory symptoms which will consist of dulness, rigor, succeeded by feverishness, quickly giving place to prostration, which increases more or less rapidly until the horse falls entirely, or more frequently is partially disabled. This may come on suddenly while the animal is standing in the stable after exercise, apparently healthy. As an example of this, I will give the two following cases which occurred in the same stable, although the horses belonged to different owners.

Case 1.—A grey mare was driven in the morning, the driver thinking it did not go quite up to its usual spirit; within an hour after returning it fell in the stall, without any noticeable premonitory symptoms excepting the languor. I saw it soon
afterwards; it was quite comatose, with a slow pulse, cold body surface, and somewhat stertorous breathing. Four hours after, the body was warmer, breathing easier, but it was still insensible. Two hours later it had returned to consciousness, and was got nicely into the sling. Next morning it was eating well, and continued to improve. On the fourth day it could stand without slings, but had still some paralysis in the hind limbs. This continued for about two weeks longer, when it was put to exercise, perfectly recovered.

The second case was a bay driving mare, which was driven early in the morning, when it seemed to be in perfect health and spirits; in about half-an-hour after its return it fell, in an entirely unconscious condition, without the slightest previous warning. I saw it soon afterwards in a deep comatose state, in which it remained throughout that day and the following night, dying the next morning between ten and eleven o'clock, or in about twenty-four hours from time of attack.

SYMPTOMS.

The symptoms may approach gradually, and this is by far the less fatal form. The horse will at first be noticed to be dull and have a staggering gait, with more and more paralysis, usually of the hind extremities. This extends over from one to three days, when the coma, generally not deep, comes on. The animal is comparatively easily roused, and unless a relapse occurs, the case almost always does well, as far as the acute attack is concerned, but the paralysis which follows this form is, in old subjects, apt to be obstinate. A case of this kind occurred in a black hack horse, which was put into slings at the latter part of the second day. During the following night it became comatose, and fell forward partly out of the slings; was returned, and remained in this semi-conscious condition for three days longer, gradually growing better, until nothing remained of the disease but paralysis of the hind extremities, which lasted some four months, when it returned to work. Relapse may occur at any time during the first six or eight days, or even later, and may prove fatal to a case which seems to be doing nicely, as in the case of a young racing-horse, which upon the first visit was found in an unconscious and somewhat excited condition; again, the
same day, it showed great improvement, was quite conscious, and appeared bright; continuing to improve during the second and third days, on the fourth the coma returned slowly; eighteen hours afterwards it brightened again, but during the following night it had another relapse, and died early on the morning of the fifth day.

Occasionally the horse is seized with all the suddenness of a spasm. The muscles of the neck, but especially those of the hind quarters, become corded, fixed, and rigid, and soon grow deathly cold to the touch. This tetanic state of the muscles may last some hours, giving way finally to flaccidity of the whole muscular system, complete anaesthesia, coma, and death in from twelve to seventy-two hours. Secondly, and this is the most common form in which the disease appears, there are premonitory signs, such as rigors, dulness of eyes, and lassitude of the whole system; followed in from three hours to as many days by paralysis, general or partial, more commonly the latter, generally affecting the muscles of the loins and hind extremities, more or less coma accompanying this stage. In some few cases delirium has ensued. The patient is frantic, beating its head against the wall or floor, as the case may be, with great violence, uttering the most horrible cries, and soon dying in great agony. I have seen one case of this kind recover, but treatment is a service of danger to the practitioner. We cannot control our patients to prevent their hurting themselves and often breaking bones during their paroxysms of madness, and the animal suffers greatly, with a small chance of recovery, so that the advisability of destroying a case of this kind at once should, I think, be taken into careful consideration by each practitioner, and decided upon with due regard to surrounding circumstances.

The pulse during the first few days is not materially altered. It may be frequent or somewhat slower than natural, as the animal may be more or less excited; but as the disease advances, and the patient becomes weaker, it increases in frequency and is strong and wiry.

Temperature of the surface of the body is lower than in health, especially in the extremities; the mouth dry; the conjunctivae are not generally injected, although in some cases they may be very much so, especially during the later stages.

The bowels are generally constipated, but may be loose, and in
rare cases the faeces may be passed involuntarily. This I have never seen except in fatal cases, and within twelve or fifteen hours of death.

The urine in appearance is generally normal, and passed without difficulty; indeed, incontinence is not uncommon, especially in mares. It may be retained from paralysis, in which case it is, when drawn, found to be of a dark colour, offensive and ropy, due to the rapid decomposition of urea, caused by unhealthy secretions from the walls of the bladder. I have met with one or two cases in geldings in which priapism was present; and in mares signs of oestrus are almost always apparent, with intense congestion of the mucous membrane of the vagina.

The breathing is more or less stertorous, seeming to depend upon the depth of the coma.

In the diagnosis, this fever should never be confounded with spinal meningitis or acute paralysis, which occurs at all times of the year, and in isolated cases, presenting much the same symptoms as the fever; but it is not so malignant, and approaches much more gradually, and, except in cases arising from mechanical injury, generally follows some other disease, such as rheumatism, purpura haemorrhagica, severe influenza, &c. It is indicated by rapid prostration, followed by paralysis, with usual but not constant constipation. The pulse and temperature are not guides during the early stages.

The prognosis should in all cases be guarded, but the more rapidly the disease develops itself, the more reason have we to dread its results. The malady progressing, the unfavourable symptoms are, deep coma, abnormally slow pulse, cold extremities, and laboured breathing.

PATHOLOGY.

The poison, having become absorbed, acts upon the great nerve centres, and may prove fatal in three ways:—1st. By shock or collapse, from the extreme amount of virus absorbed: 2d. More slowly, by blood poisoning: 3d. From a mal-nutrition of parts, consequent upon deranged nervous function.

TREATMENT.

The supply of blood to the spinal cord is undoubtedly too great, and must be lessened; but this cannot be safely accom-
plished by bleeding in these cases. The first thing is, if possible, to raise the patient, and put it into a comfortable sling, or if it be unconscious, so that this is impossible, make a large thick bed of straw, place the patient on it, and see that it is carefully rubbed and turned as often as every two hours. This must be strictly attended to, for the position of the animal, as well as the disease, tends to improper circulation of the blood, from which we can expect nothing but bad results. Unless the patient is slung within twenty-four hours from time of attack, there is but slight hope for a recovery. Having got it into the sling, our treatment is (if the horse will bear it without showing signs of irritation) to have it well brushed, especially about the extremities; it must be well clothed, and its legs dry bandaged with flannel rollers. The appetite, if the horse is conscious, is generally good. It should be allowed a fair quantity of good soft food, such as boiled oats, carrots, &c., and a small quantity of hay; remembering always that the bowels are apt to be costive, and that it is better for the patient if they can be regulated without physic.

As to the medical treatment, there is a great diversity of opinion amongst practitioners as to what is the right mode. Some bleed and purge, but with bad results; others blister the spine anterior to the seat of inflammation (as indicated by pressure) with a mixture of turpentine and mustard, with the idea that the disease is on a march from the brain, and that this will put an effective barrier in its path. Belladonna, colchicum, sal ammoniac, carbonate of ammonia, and many other substances, have been used with better or worse results. The use of atropine, injected subcutaneously, in conjunction with ergot given in the food, I have found very efficacious, if followed by stimulants and tonics during convalescence, but the stimulants must be used cautiously at first.

Whatever treatment is adopted, the aim should be to reduce the supply of blood to the cord, and keep the general circulation in as normal a condition as possible, at the same time keeping up the animal strength as much as we are able. If after two or three days the bowels continue costive, and do not respond to an enema, a physic ball may be given. From the paralysis the catheter may become necessary.

The water treatment, as recommended by Dr. John Chapman,
is well worthy of a trial, and will be very valuable in our practice, if it can be made to act on animals as it is said to do on man. He claims to have discovered that a controlling power over the circulation of the blood exists in the brain, spinal cord, and ganglia of the sympathetic, and that the agency of these nervous centres, in every other organ of the body, can be regulated by means of cold and heat applied to different parts of the back. In this manner, the reflex excitability or excito-motor power of the cord, and the contractile force of the arteries in all parts of the body, can be immediately modified. In order to lessen the excito-motor power of the cord only, he applies ice, in an india-rubber bag about two inches wide, along that part of the spinal column on which he wishes to act. On the same principle, the vitality of the cord may be increased by employing hot water and ice alternately, each in a proper bag, when very energetic action is required; but if less vigorous effects are alone necessary, he uses ice-water only, resorting to it several times a day, for a short time on each occasion, with a long interval between each application. Thus, for example, intending to direct a fuller and more equable flow of blood to the brain, he applies ice to the back of the neck and below the scapulae; increased circulation in, and warmth of, the upper extremities will thus be induced. In like manner the thoracic and abdominal viscera can be influenced by applications to the dorsal and lumbar regions; while the legs and coldest feet may have their circulation so increased, that they become thoroughly warm, by the ice-bag being applied over the lower part of the back.
CHAPTER XXXIII.
ERUPTIVE OR PETECHIAL FEVERS,
USUALLY ASSOCIATED WITH EPIZOOTICS, ALTHOUGH THEY DO NOT THEMSELVES USUALLY ASSUME EPIZOOTIC CHARACTERS.

UNDER the above head I am induced to classify two diseases, usually termed blood diseases, namely, Purpura Hæmorrhagica and Scarlatina.

PURPURA HÆMORRHAGICA, DIARRHÆMIA.

This disease was arranged in the first edition of this work in the same group as the charbonous affections, which in several characteristics it simulates; but the life history of the morbid processes, the causes, the non-contagiousness, and the absence of organisms in the blood in this disease separate it from anthrax.

Fault has been found with the term "purpura hæmorrhagica," and Delafond has named the disease "diastahæmia." I think the term is more objectionable than purpura, as it merely implies a standing apart or a separation of blood; and were I to venture upon a new term, I would suggest "diarrhæmia"—Gr. δην, through; ἓρω, I flow; αἷμα, blood; or a disease characterised by breaking up of the blood, and ecchymosis.

Definition.—An eruptive non-contagious fever of an intermittent type, usually, but not uniformly, occurring as a sequel to another disease.

Pathology and symptoms.—The primary manifestations are often uncertain. In some instances the earliest symptom may be the expression of pain in one or more limbs, with but slight swellings, which, however, become more pronounced in a very short time. In other instances, the approach of the disease is shown by the appearance of a few petechial spots in the nostrils
or papulae on the skin, whilst in other cases the malady is fully manifested in a very short period.

Similar to its analogue anthrax, purpura is a disease in which the blood is gravely altered, associated with extravasations, effusion of red coloured serum, preceded and accompanied by constitutional disturbance, languor, debility, sudden elevation of temperature to 104°-106° F., or even higher, the alternations of temperature being very great. The alternations in the following table are from the clinical report of a case which died at the College:—

</table>

On the last day there was a copious discharge from nostrils and mouth. Horse kept on its legs till the last, and dropped down dead without a struggle.

The capillaries of the skin and mucous membranes are especially implicated in the congestions, and at all times there is a tendency to gangrene and decomposition of the extravasate, the products of which, being absorbed into the circulation, give rise to septicemia and death. In some instances, thrombi form in the vessels of the parts more extensively and persistently swollen, and induce sudden death by embolism in the vessels of some vital organ, or a more protracted one by pyaemia.
In other instances, effusion poured out into the lungs is converted into a fibrinous exudate, which tends rather to a retrograde metamorphosis than to organisation, forming a caseous or semi-caseous mass, and interfering most materially not only with the integrity of the organ, but with the general health of the horse.

The more particular symptoms are petechial spots, of a dull mulberry or purple hue, on the visible mucous membranes. There is very often haemorrhage from the mucous surfaces, the discharged blood being dark in colour and often foetid in odour. Extravasations also occur in the substance of several viscera, more particularly the lungs, spleen, and liver. The limbs, lips, and other depending parts of the body swell, the swelling arising from extravasation of blood into the areolar tissue, and from the transudation of serum, and feebly coagulable lymph. The swellings are characteristic: they are generally uniform, extending perhaps the whole length of a limb, and terminating superiorly very abruptly, as if a cord had been drawn around the part. They are painful, hot, hard, and in those portions where the skin is barely covered with hair, as the lips, nostrils, and inside of the thighs, shining; and if uncoloured, petechial spots are seen upon its surface, but where it is dark-coloured no spots are discernible. Vesicles of about the size of a pea are present upon the lower parts of the limbs, around the hock and fetlock joints; these burst and discharge an amber-coloured acrid serosity that scalds and exoriates the surface of the skin over which it flows. Cracks and fissures appear at the flexures of the limbs, from which an unhealthy amber or purple coloured discharge issues. Swellings appear about the sheath, abdomen, and breast; these, in the earlier stages often disappear from one part of the body and reappear in another. In many instances the face, lips, nostrils, and eyelids become fearfully swollen; the swelling being tense, uniform, and ending abruptly about the forehead. This swelling of the head is apt to cause a fatal termination by interfering with the respiratory function; the swollen nostrils diminishing the calibre of the nares, great dyspnoea is thus induced. By interfering with the movements of the tongue and jaws it also prevents the animal from feeding, and thus becomes an additional cause of debility. The skin over the swollen parts has a great tendency to slough, leaving large open and unhealthy looking sores, which
discharge an unhealthy, fetid sanies. The pulse is feeble, often fluttering, dicrotonous—double, and there is great prostration of the vital powers. The bowels are at first generally constipated, but purgation is easily excited. Sometimes the feces are mixed with blood, and abdominal pains are often present. In some instances there is soreness of the throat; but in purpura it is an accidental complication, and absent in the majority of cases. There is very often a hoarse or hollow cough, and a discharge of coffee-coloured fluid from the air passages. The petechial spots on the nose frequently slough, and leave a raw surface, from which issues an abundance of dark-coloured sanies, causing a snuffling sound in the nasal passages; and in some instances the tongue has been found swollen, with large, dark-coloured vesicles on its surface, containing much fetid material.

Some cases will commence to improve under proper treatment on the third or fourth day. Others take a much longer period, the fever being of a remittent character, and at all times the animal is liable to exacerbations from very trivial causes.

It is with difficulty that the animal can be made to move, owing to the stiff and painful condition of the limbs; it will often stand rooted to one spot for hours or even days together.

The urine is generally high, often dark-coloured, and emits a strong odour of ammonia; it contains much solid matter, and if kept in a vessel very soon undergoes decomposition.

In many instances the enteric complications are very grave and important, and in every case there is a danger of sudden extravasation into the intestinal mucous membrane and alimentary canal, the extravasations being so excessive as to cause rapid death from internal hemorrhage.

Causes.—In the great majority of instances purpura occurs as a sequel to some debilitating disease, more particularly catarrhal fever, and its origin can in most instances be traced to bad ventilation or drainage. When an animal suffering from catarrhal fever is kept in a well-ventilated, well-drained stable, and otherwise properly cared for, purpura is scarcely ever seen; but if such an animal is housed in a badly drained, ill-lighted, and defectively ventilated stable, in fact, when it is compelled to inhale the products of decomposing urine, feces, and of its own breath for several days together, the blood becomes so empoisoned with affection products that it loses its integrity, accumulates in the
capillaries and smaller veins of loose structures, more particularly in the depending parts of the body, constituting those swellings which are so characteristic of purpura, and when withdrawn from the body it is only feebly coagulable. Again, I have witnessed the occurrence of the disease in horses apparently recovered from influenza and strangles, placed to work or taken to exercise while still debilitated.

In rarer instances purpura may appear as a primary disease, traceable to defective drainage, ventilation, or bad food.

I have witnessed a few instances where death has occurred in the horse without the usual external manifestations; but where the post mortem examination revealed many of the characteristics of this blood disease, sometimes the animals have suffered from enteritis, sometimes they have sunk without manifesting any pain, have refused food, hung down their heads, the surface of the body being cold, they have become pulseless, and died in a few hours.

In one instance the animal suffered from several convulsive fits for three days, and died in one of them, the post mortem revealing darkness and fluidity of the blood, petechial spots on several internal organs, more particularly on the cerebro-spinal meninges. In this, as well as in the other cases, a careful examination of the tongue prior to death enabled me to detect the nature of the disease. This organ had a peculiar mulberry, purple, or claret colour; and that was the only symptom of blood alteration that could be detected, the Schneiderian membrane and conjunctivæ being merely injected.

It may safely be concluded that the causes of purpura are of a septic nature, and are due to the absorption of products of decomposition extrinsic to the body; to the severity and rapidity of tissue change within the body, either owing to a previous disease or debilitating circumstances, and to their accumulation when naturally generated, owing to impairment of the excretory organs.

The acute symptoms are generally of a remittent type, and when the practitioner is consoling himself with the belief that the animal is improving, it often happens that at the next visit the symptoms have become much aggravated, and the patient is rapidly carried off, dying perhaps on the second, third, or fourth day. In many instances again the acute
symptoms subside, and the animal begins to feed, but rapidly becomes emaciated, with great muscular debility, and inability to rise after lying down; these symptoms being accompanied by, or independent of, extensive sloughings of the swollen parts. When sloughing takes place the skin and subcutaneous tissues assume a dry, leathery appearance, and separate tardily from the subjacent living structures; the discharge from the nose may continue, and the animal may die from repeated exacerbations, exhaustion, pyæmia, glanders or farcy, or from gangrene of the lungs, on the third, fourth, or even sixth week after attack. In some cases abscesses may be detected in various parts of the body, in the glands; or the lungs, liver, kidneys, &c., may be infiltrated with purulent accumulations.

The post mortem appearances of those which have died during the early and acute stages of the disease are as follows:—

Darkness and fluidity of the blood; the subcutaneous tissues of the swollen parts filled with dark red or cinnamon coloured, feebly coagulable exudate. Dark spots will be found on the theae of muscles, and in the muscular structures of various parts of the body. They do not penetrate deeply into the muscular tissues, but the stain gradually decreases as the muscle is cut into, and some trace of it may be found to extend perhaps an inch into the thicker muscles. The various serous membranes—the pleura, endocardium, pericardium, and cerebral meninges—will be covered with petechial spots, the mucous membranes stained black or blackish-green. This colour will not be uniform, but interspersed with petechial spots, and in some instances the membranes will be covered with a thick layer of imperfectly coagulated blood; and, again, cinnamon-coloured, gelatinous coagula will be found on the heart, along with a serous effusion, filling the pericardial sac. The dark spots become black on exposure to the air. The blood has a violet tint, and is variously altered on exposure; in some instances it reddens, in others, like the spots, it becomes darker. Kept in a vial closely corked, it will retain its fluidity for a very long period. (Healthy blood, to which ammonia has been added, can scarcely be distinguished from the blood of purpura.)

I have a beautiful drawing, given me by Mr. C. Stephenson, Newcastle, of a brain and spinal cord of a horse which died comatose from purpura, showing the arachnoidian cavity, cerebral and spinal, filled with extravasation.
The mesenteric and other glands are generally congested, friable, and enlarged; the liver, spleen, and kidneys are variously altered,—sometimes merely congested, sometimes enlarged, softened, and containing a large quantity of dark-coloured fluid blood; the lungs dark, enlarged, pigmented, and more or less decomposed; the bronchi and trachea filled with dark-coloured extravasation.

Treatment.—It is useless attempting to treat this disease without first removing the animal from all offensive smells, bad drains, and bad ventilation. Pure air, light, warmth, and comfort are the first essentials. Secondly, it must be borne in mind that the great danger of a suddenly fatal termination is from extravasation into some internal organ, or even into the subcutaneous tissues. Some cases may die from the empoisoned condition of the blood, without the occurrence of any extravasation or even congestion, but these are rare compared with the first named.

For the purpose of overcoming this tendency to extravasation, styptics, such as turpentine or ergot of rye, or astringents, as the tincture of the terchloride of iron, are sometimes successfully employed. If these are given in combination with an oleaginous purgative, any astringent effect which they might otherwise exercise on the alimentary canal is prevented. It must, however, be remembered that extravasations depend more upon the condition of the blood than upon the blood-vessels, and remedies which are calculated, either by their antiseptic or oxidizing properties, to alter the abnormally fluid condition of the blood, are better calculated to attain the object than those which merely act upon an effect of the disease. For this reason, the chlorate of potash has been prescribed, and with marked results. Whether this salt acts as a direct antidote to the septic poison or not, is a matter which I cannot explain. It is a fact that blood, when drawn from an animal suffering from purpura, or from one in a state of health, has its coagulating properties much increased when a small quantity of this salt is added to it. I have kept blood thus treated in a firmly coagulated condition for more than a year. The coagulation is so rapid and so firm that scarcely any serum is pressed out; and, what is most remarkable, there is but little contraction of the clot.

Acting upon my experience as to the effect of this salt in
promoting coagulation, and at a time when physiologists believed that fibrin was a natural constituent of the blood, I commenced to treat purpura with the chlorate, for the purpose, as I then supposed, of increasing the fibrin in the blood, and thus prevent the occurrence of congestions and extravasations. The result was most satisfactory; the swellings rapidly diminished, and restoration to health ensued in the great majority of instances. One ounce in the twenty-four hours is quite sufficient after the first dose, which may be from one-half ounce to an ounce, given at once. If more than this be given, intestinal irritation is apt to be produced, and the disease thus complicated. In addition to the administration of the chlorate, it is necessary that the excretory organs perform their functions, in order that the morbid material and the products of tissue changes be eliminated from the system; for this purpose oleaginous aperients are to be administered. Metamorphosis of tissue, which is very great, as seen by the rapid emaciation, and by the quantity of solid ingredients in the urine, is to be diminished by small doses of alcoholic stimulants, more particularly the spirits of nitrous ether, which is more congenial to the horse than any other spirit. Ammonia is to be avoided, as it, or a product approaching it, is already superabundant in the blood. I do not recommend large and repeated doses of stimulants, my experience leading me to the conclusion that in the horse they always do much harm.

Beyond this, I think medical interference is uncalled for; and it may be stated here that much advantage is derived from non-interference, both in this and many other ailments of the lower animals.

The convalescence is very often prolonged, great prostration remaining for a long time. The animal must therefore have a liberal supply of good food—oats, beans, hay, &c.—and be carefully groomed and tended. The mineral tonics may be administered, and daily and carefully regulated exercise given.

External treatment.—If the head be much swollen, and there be a difficulty in breathing from tumefaction of the nostrils, continuous cold sponging must be ordered. The sponge may be dipped in cold water or in some weak astringent solution—vinegar and water, or the terephluride of iron tincture, largely diluted; if the cold sponging fails to reduce the swelling, warm
may be substituted, particularly if the weather be very cold; but beyond doing this to the head, I am of opinion that all other interference does much mischief.

The swellings are but the result of the condition of the blood, and when the latter is restored to its normal standard the swellings will disappear. Indeed, an abatement of the swelling in one part of the body is often succeeded by tumefaction in some other, and perhaps more important structure or organ. The swellings are generally metastatic, and when they are confined to those parts of the body where they cannot endanger life, it is far better to leave them alone.

Puncturing the swellings is usually recommended and generally practised. In very severe cases of purpura admission of air into the degraded tissues causes deep and sometimes intractable sloughings. Punctures are, therefore, inadmissible.

If there is dyspncea from swelling of the throat or nostrils, tracheotomy must be performed, and it ought always to be done early, as it is essential that the horse be enabled to breathe freely; in fact, it must not be forgotten that oxygen in abundance is required by the vitiated blood.

**SCARLATINA—SCARLET FEVER.**

A febrile disease, characterised by an eruption on the skin, petechial spots on the nose, soreness of the throat, and sometimes suppuration in various parts of the body, particularly in the submaxillary space.

Unlike the scarlatina which attacks the human being, it is a non-contagious disease, generally attacking but one or two horses in a large stud, amongst which some form of epizootic disease is at the time prevalent.

Dr. Copland, in his *Medical Dictionary*, article “Skin,” says—"First, That scarlatina was originally a disease of the horse, and that it formerly occurred, and has recently occurred, epidemically or as an epizootic among horses. Secondly, That it was communicated in comparatively modern times from horses to man. Thirdly, That it may be, and has been, communicated also to the dog.” If this be true, scarlatina of the present time must be very different from what it has been in the past. I have seen numbers of horses suffering from it, but in no case did it ex-
hibit any tendency to spread by contagion or infection; and I am of opinion that it is impossible to transmit it from the horse to any other animal.

Scarlatina is divided by medical writers into—(1.) Scarlatina simplex; (2.) Scarlatina anginosa; (3.) Scarlatina maligna; and (4.) Scarlatina latens.

Of these the two first are observed in the horse, what is called the malignant form being identical with purpura; it is quite possible, however, for any of the forms to degenerate into purpura.

Scarlatina is usually associated with epizootic catarrh, and occurs in animals that have been for some days suffering from that disease; and the production of such an alteration in the blood as induces the scarlatina is due to defective ventilation or drainage of the stable in which the animal has been kept, or to over-crowding, by which the air becomes loaded with decomposing animal matters. Sometimes a weak constitution will convert a catarrh into scarlatina, and the severity of an epizootic disease may alter the blood, and give origin to scarlatina.

Semiology.—1. Scarlatina simplex.—On the third, fourth, or even as late as the sixth day after the commencement of epizootic catarrh, the animal is seen to be covered with blotches, upon the face, neck, body, and extremities. The blotches elevate the hair, but in many places there is scarcely any elevation of the skin, for if the hand be passed lightly over the apparent swellings, the skin is felt but little altered. In other parts of the body, particularly upon the inner aspect of the thighs, actual elevations of the skin in the form of rounded pimples can be both seen and felt. The nasal membrane will be covered with scarlet spots of variable size, and there will be a discharge from the nostril of at first a thin serous mucus, which afterwards becomes yellow or yellowish brown. The limbs are generally swollen, and the animal stiff in consequence. In some instances, no eruption is present, and the only evidence of scarlatina is found in the Schneiderian membrane, and perhaps the membrane of one nostril only will be covered with minute scarlet spots that escape the observation of all but the practitioner.

Soreness of the throat is almost a constant symptom, and if it has preceded the rash, it will in all probability be more or less increased; but it by no means follows that soreness of the throat will appear concomitant with the rash. In a few days
the rash and scarlet spots begin to disappear, and on the rash declining, some desquamation of the cuticle takes place, the skin being scurfy, and the coat dirty for some time afterwards.

2. Scarlatina anginosa.—The symptoms at first may be those of the simple form, which, instead of disappearing, may continue to increase in severity. The limbs rapidly swell, the swellings appearing in lumps or masses, large, hot, painful, and numerous. These swellings may also appear on the body and face; they are inconstant in their seat, often disappearing from one place and appearing at another, whilst the intervening spaces may be covered by a rash similar to that of urticaria, and by blotches not elevated to the touch. The skin covering the blotches will often be found moist, and an amber-coloured serosity will ooze from it. The petechial spots on the membrane of the nose increase in size, and become more intense in colour, assuming a tinge of purple, more especially at their centres; in other cases they coalesce, forming one large block, which covers the whole nasal chamber.

The soreness of the throat now becomes very great, and is accompanied by a loud moist cough, and at each cough large quantities of a yellowish-red mucus are discharged through the nose and mouth. There is difficulty in swallowing, and in some cases in breathing, the inspiratory act being accompanied by a roaring noise, and by a snuffling nasal sound. The submaxillary lymphatic glands become enlarged, tender, and inflamed, and suppuration occurs after the other symptoms have begun to disappear.

In favourable cases the soreness of the throat will recede with the eruption about the fourth or fifth day, whilst in others it will remain for some days after the disappearance of the rash. In all cases that recover, however, both the exanthem and angina will have disappeared by the ninth or tenth day, leaving the animal weak, emaciated, with swollen limbs, and in a more or less unthrifty condition for some time longer.

The fever is usually proportioned to the severity of the sore throat, and very often, but not always, to the rash. In slight attacks, the fever, rash, and angina are of a mild character; but in the severer forms they are proportionately grave. The pulse, which is always of a weak or feeble character, varies from 60 or 70 in the mild, to 90 or even 100 in the severe forms; the respiratory
SCARLATINA.

movements are accelerated, and very rapid when congestion of the lungs is present; the urine is scanty, and of a thick yellow or brownish colour, smelling strongly of hippuric acid, and quickly becoming ammoniacal; the bowels are constipated, but diarrhoea is easily induced.

Mr. Haycock describes the malignant form. I am of opinion however, that what he thus describes is purpura, or a combination of purpura and scarlatina.

For a number of years I was of opinion that purpura and scarlatina were one and the same disease, but I have had occasion to alter this opinion, as typical cases of both diseases are not uncommon in Edinburgh. The distinguishing differences between the two diseases are to be found in the character of—1st. The petechiae, which, in scarlatina, are composed of minute dots, forming a blotch by coalescence; the spots may be as large as in purpura, but each is composed of several smaller ones; they are scarlet in pure scarlatina, of a dark purple in purpura. 2d. The sore throat. This is never absent in scarlatina, and but rarely present, unless it is a symptom of previous disease, in purpura. 3d. The swellings. In scarlatina, these are at first in the form of lumps or masses, whereas in purpura they present an even surface, occupying the face, or a whole limb or limbs, and terminate abruptly above, as if a cord had been drawn tightly around the part. 4th. Scarlatina is often associated with swelling and perhaps suppuration of the glands, whilst in purpura this is not present; and finally, the latter disease is characterised by a tendency to sloughing in various parts of the body, and occasionally by gangrene of some extreme parts of the organism, such as the ears, which will present a shrivelled and blanched appearance, become dry, and slough, leaving a raw, unhealthy surface. The animal temperature may not distinguish the one disease from the other. If scarlatina be severe, the thermometer may register 103°, or even higher; in purpura this would indicate a mild attack.

Scarlatina is sometimes followed by inflammation of the joints, which is supposed to be rheumatic in character, and by suppuration in various parts of the body; but I am not aware that it is succeeded by renal dropsy, or associated with albuminuria, as in the human being. There is generally more or less oedema of the limbs, breast, and abdomen, but these are not
necessarily due to any renal complication, as they are common sequelae to most debilitating diseases in the horse.

_Treatment._—In the milder forms of the disease it is sufficient to keep the animal in a warm, well-ventilated, light, loose box, to feed it on laxative food, and give small and repeated doses of the nitrate of potash, hyposulphite of soda, or chlorate of potash, in the food or water. The body must be clothed according to the weather, and the general comfort of the animal attended to.

In the graver forms, the animal must be carefully watched, more especially with regard to its breathing, for in some cases the glottis and other structures of the throat rapidly swell, the larynx becomes constricted, and the animal may die from suffocation. Whenever this is threatened, tracheotomy must be performed; and in all cases where the breathing is difficult, and accompanied by a loud roaring noise, this operation is to be resorted to, in order that the animal may obtain pure air to oxidize its already impure blood.

The throat is to be repeatedly bathed with hot water and enveloped in warm poultices, and the animal made to inhale the steam of hot water. The mouth is to be frequently washed out with salt and water, and if the coryza is excessive some of it may be applied to the nose. If the face and nares are swollen, they must be frequently bathed with cold water, and afterwards dressed with some astringent lotion, such as a solution of the tincture of perchloride of iron. If the bowels are very torpid, a gentle laxative may be administered, such as one pint of linseed oil, but active purgation must on no account be induced; the nitrate of potash may be given freely in the food or water, and abundance allowed of the latter, which must be cold and fresh. If signs of purpura supervene, the chlorate of potash must be substituted for the nitrate. If much depression is present, draughts of spirits of nitrous ether may be given, provided deglutition is not difficult; but if the act of swallowing causes pain and cough, nothing should be forced upon the animal, or suffocation may ensue. Indeed, where the throat is very sore, even the oil must be withheld, and the bowels relieved by enemias, or by the sulphate of magnesia dissolved in the horse’s water. If he will drink this, it has a very good effect, but many horses will not drink at all if salts are dissolved in their water. After the first few days milk, or milk with eggs, is to be
allowed in abundance, in order to support the animal strength. When the secretions are restored to their natural condition, and the soreness of the throat a little abated, a small ball containing carbonate of ammonia—the ball being well oiled—may be given two or three times a day with great benefit, and later on the mineral tonics, with bark or quinine. If soreness of the throat and cough remain after the subsidence of the rash and fever, ulceration is to be suspected, and this can occasionally be detected by an examination with the oral speculum.—(See Principles and Practice of Veterinary Surgery, page 511.) It may be combated by a blister to the throat, or by direct application of the nitrate of silver solution to the part by means of a sponge tied to a piece of cane.

When suppuration has occurred, the abscess is to be opened, as the abscesses of scarlatina often become languid, and do not burst readily.

Whenever the fever abates, and other signs of convalescence appear, food of the most nutritious quality must be allowed in moderate—not over-abundant—quantity.

Exercise should not be enforced until all febrile signs have disappeared, and the animal has to some extent regained its strength; even then much exercise is to be strictly forbidden. I have seen the most severe and rapidly fatal purpura caused by exercising the animal too soon and too severely.

I have said nothing about the treatment of the external swellings of the limbs. I am of opinion they should not be interfered with; as they are but expressions of a condition of the blood which does not endanger the life of the animal, and will disappear spontaneously.

The post mortem appearances are similar to those of purpura, with the addition of inflammation and swelling of the throat.
CHAPTER XXXIV.

SPORADIC DISEASES.

(1.) CONSTITUTIONAL DISEASES.

(4.) RHEUMATISM.

ACUTE RHEUMATISM, OR RHEUMATIC FEVER.

Definition.—An inflammation of the fibrous structures of the joints, tendons, ligaments, thecae of muscles, or of the heart and closed cavities, due to a specific condition of the blood, and accompanied by fever, stiffness, and lameness. The inflammation is metastatic or erratic in its character, disappearing from one part of the body to reappear in another, without any appreciable cause. The inflamed parts are generally swollen and hard, but in some instances no swelling can be detected.

Characteristic of rheumatic inflammation both in man and the lower animals are—(1.) The rarity of suppuration. This process may and does sometimes occur, especially in horned cattle, from inflammation of the superficial coverings of the diseased tissues, caused by external bruising, or the application of powerful external irritants. (2.) The occurrence of cardiac complications. (3.) A natural predisposition or diathesis, which predisposes to the malady without any ostensible cause. The form of the disorder in this instance is of a less acute nature, but may become acute by the addition of any trivial cause of disease.

Etiology.—The application of cold; damp; or it may result from other diseases, as epizootic pleurisy, contagious eczema, or from a natural predisposition without apparent cause.

Semiology.—The symptoms of rheumatic fever are as follows:—Sudden lameness, with or without swelling of some particular articulation, such as the stifle, hock, or fetlock joints, the flexor tendons, immediately below the knee or hock in the seas-
moidean bursa, the shee of the muscles of the loins and quarters, or of those of the thoracic walls, constituting pleurodynia. The lameness may be preceded by some febrile disturbance or a malaise condition, expressed by yawning, dulness, or dejection. The lameness often disappears from one part of the body and suddenly reappears in another. Very often the lameness is symmetrical, that is to say, it will be due to inflammation of the same joints in both legs, say in two stifle or in two hock joints. The fever is acute and athenic when it is not preceded by some epizootic disease; the pulse is hard and unyielding; the mouth hot and dry. The urinary secretions are impaired and altered; the urine, which in health, when tested with litmus paper, gives an alkaline reaction in the herbivora, is neutral, or more or less acid, and if microscopically examined is found to be loaded with hippurates of soda and ammonia, and hippuric acid.

There is generally some degree of costiveness, and if blood be drawn, the coagulum will be firm and large; indeed, in no disease is there such a rapid and sensible increase of fibrin in the blood as in acute rheumatism—in some cases as much as 10 parts in 1000 of blood have been found. The swellings of the affected parts quickly assume a hardness due to exudation, but, as already stated, suppuration rarely occurs. The elevation of temperature is sometimes very great—104°, 105°, or 106° F.; when over 105° F. it is always indicative of great danger. I have known it as high as 109° F. in a cow.

CHRONIC RHEUMATISM.

The symptoms of this form are mere modifications of those of the former, except that fever may be entirely absent. It is, however, much more persistent, less metastatic, and leads to alterations of structure, consisting of ulceration of articular cartilage, sburnation of the bones, and the formation of osteophytes, much more commonly than the acute, an attack of which may leave the animal quite well at its termination. Sometimes, however, the acute degenerates into the chronic, and an animal subject to the chronic is very often attacked by the acute form. In chronic rheumatism not only are the white fibrous structures altered, but the bones in various parts of the body may become subject to various pathological changes; tumours or bony excrescences form on the bones of the pelvis, spinal column, and in the fringes of
the synovial membranes; distortions also occur. I have seen the neck twisted by large bony tumours on the cervical vertebrae, arising from this cause; also enlargement and ankylosis of the joints, ulceration of articular cartilages, particularly of the navicular bursa, eburnation of the exposed bony extremities, and ossification of the walls of the heart. The soft structures above and below the affected joints in horned cattle sometimes swell, suppurate, and continue to discharge pus for a lengthened period, the animal rapidly wasting, and finally becoming worthless.

Both in the acute and chronic forms the pericardium, endocardium, and cardiac valves may become inflamed. This complication, however, is of much more frequent occurrence during an acute attack. The pulse becomes jerky and wiry, the heart's action short, sharp, and angry, the cardiac impulse is often awanting, the pulse intermittent, and a to-and-fro sound accompanies the heart's movements.

PATHOLOGY.

What the true nature of the so-called rheumatic poison really is, pathologists are not agreed upon, some asserting that it is lactic acid, whilst others are not satisfied on this point. It is certain, however, that the urine both in man and in the lower animals assumes an acidity which is quite unnatural; but the acid found in it is not the lactic, but the uric and its salts in man, and the hippuric and its salts in the herbivora. The suggestion that rheumatism is due to the presence of an excess of lactic acid originated with Dr. Prout. The lactic acid originates by the conversion of the starch of the food into lactic acid, which then combines with oxygen to form carbonic acid and water; and anything which interferes with this change may lead to the accumulation of the acid in the system. Dr. Garrod, however, found the serum of the blood distinctly alkaline in thirty-five cases of rheumatism in the human being.

In every case of rheumatism met with by myself, and where an examination of the serum has been made, it has been found alkaline. The only experiments which go at all to establish the connection of lactic acid with rheumatism are those of Dr. W. B. Richardson, who injected lactic acid into the peritoneal cavity of dogs, and found that it caused death, not by inducing
peritonitis, but peri and endocarditis, with thickening of the cardiac valves; the post mortem examination showing a red thickened state of the mitral valve, with fibrous bead-like deposits on its surface; the endocardium lining the left ventricle intensely inflamed, resembling bright red velvet, and the aortic valve of a deep red colour, and its borders thickened and everted; the pericardium red, injected, and covered with lymph.

Dr. Fuller believes the poison of rheumatism to be identical with some natural excretion of the skin. The researches of Dr. Parkes lead him to conclude that the disease is due to some substance rich in sulphur; whilst other writers and observers look upon rheumatism as simply an inflammation of the fibrous and serous membranes, the predisposition to which arises from deficiency of healthy tone in these textures, rendering them liable to be inflamed by the influence of a variable temperature. The character of rheumatism, more especially its metastatic tendency, and the symmetrical development of its symptoms, tend to show that an alteration in the blood exists; the only constant alteration is, however, the great increase of fibrin. We are thus led to the conclusion that, whatever the morbid material may be, it is one formed within the economy, and due either to a faulty secondary digestion and assimilation, or to an abnormal metamorphosis of tissue and the retention of the products of such metamorphosis within the animal body. In man copious perspiration is a characteristic sign of rheumatism, and it is to be noticed that this perspiration has an acid or sour smell. In the lower animals perspiration may be copious, but sourness of smell is not appreciable.

In rheumatic endocarditis in man, the left side of the heart is only affected, as a general rule; and it has been inferred by Dr. Richardson that the chemical change whereby the morbid matter of acute rheumatism is produced, is completed in the pulmonary circulation; that when the blood in the pulmonary capillaries is exposed to the air, the acid quality of the poison is produced; that the poison thus formed is carried by the arterial circulation to be disposed of by decomposition or elimination, or both; and that it does not return as an acid by the veins, but simply as a product which admits of retransformation in the pulmonic circuit into the acid state.
TREATMENT.

In the Horse.—A gentle laxative may be given with advantage, and there is no such objection to an aloeetic purge as in some of the diseases which have been enumerated. If the pain be excessive, opium may be combined with the purgative, and repeated once or twice a day. To prevent its constipating action on the bowels, the opium may be combined with calomel, but calomel should not be given until the bowels are "set" after the purgative. If the pain is not excessive, aconite and the nitrate of potash are more suitable than opium, and in all cases the nitrate of potash is to be freely administered in order to alter the character of the blood, to act upon the excretory organs, and to influence the vascular system. I am of opinion that the nitrate has a more powerful influence on the disease, and is less debilitating than the bicarbonate of potash or the liquor potassse. In combination with the nitrate, colchicum has a favourable effect, and in cases where debility is not great, it should be substituted for the aconite about the third or fourth day. If the sufferer be strong, young, and in good condition, a moderate bleeding is usually prescribed; as a rule, however, the conditions do not warrant the abstraction of blood. Indeed, it is now generally agreed that although bleeding, by relieving congestion, may give temporary relief, it enhances future suffering and danger, by increasing the irritability of the heart, and consequently predisposing it to rheumatic inflammation.

Local treatment.—If the pain in the inflamed parts be very great, it may be advisable to endeavour to relieve it by warm fomentations, and the application of a liniment, containing some of the extract of belladonna, opium, or aconite; but valuable time should not be wasted if these afford no relief, and blisters are to be freely applied to or near the inflamed parts. The treatment by blistering is called that of stimulation, and those who advocate it most strongly use it only. According to Dr. Herbert Davies, physician to the London Hospital, the action of blisters, by promoting a serous discharge from the blistered surface, affords a ready means of exit to the rheumatic virus.

The success of this treatment depends upon the amount of vesication produced by the blister; and in order to promote the free flow of serum, the blistered parts are to be subsequently
covered by linseed meal poultices. According to Dr. Davies, the blister treatment causes a speedy diminution in the frequency of the pulse, rapid subsidence of the joint affection, and lessens the liability to cardiac inflammation. Within twenty-four hours after the removal of the blister, the urine is stated to become alkaline in reaction.

Dr. Davies does not apply the blister upon, but near to the inflamed part. I can speak with great confidence of the benefit of treatment by blistering in the lower animals; the blisters are, however, quite as effectual when applied to the inflamed parts.

In the Ox.—The same external treatment is applicable as in the horse; the nitrate of potash may, however, be given in larger doses, and the bowels acted upon by the sulphate of magnesia or soda instead of aloeis. Cows will often, when suffering from rheumatic fever, refuse to rise from the recumbent posture. In such cases repeated change of bedding is absolutely necessary; great cleanliness, dryness, and comfort must be secured, and the inflamed joints wrapped in dry flannel, in order to prevent bruising and the occurrence of the suppurative process.

With regard to cardiac complications, I think the cow is not quite so liable to suffer as the horse: this is, however, a matter of opinion merely.

If suppuration occur in or near to an articulation, it is best at all times to put the ox or cow out of its sufferings, as recovery seldom or never takes place.

The diet in all cases, if the animal be not already debilitated by previous disease or other cause, must at first be light and easy of digestion, as mashes and hay, or green food, if in season; as the fever subsides, stronger food may be cautiously allowed; and if depression be a marked symptom, cinchona and ammonia are to be prescribed in suitable doses.
CHAPTER XXXV.

SPORADIC DISEASES—continued.

(1.) CONSTITUTIONAL DISEASES—continued.

(2.) TUBERCLE.

Until recently, tubercle was divided into several varieties, namely, grey, yellow, infiltrated, encysted, and calcareous. It is now, however, admitted that all but the first have no relation to tubercle, further than that they may result from its retrograde metamorphosis, as well as from that of many non-vascular exudates and growths.

Virchow has limited the term "tubercle" to a definite growth, which at first consists of a grey, semi-transparent nodule—the grey tubercle—also called miliary tubercle, and the "grey granulations of Bayle." Some pathologists object even to this restriction, and would do away altogether with the term "tubercle," as being indefinite and unsatisfactory, and Dr. Bastian has proposed to substitute the term "granulia," in order to do away with many misleading suggestions connected with the old name.

Admitting the proposition that tubercle presents itself in but one definite form, and that all departures from this are due to the process of degeneration, which is common to it as well as to other products, tubercle may be defined to be a non-vascular, grey, semi-transparent nodule, of firm consistence and well-defined spherical outline, varying in size in the lower animals from a millet seed to that of a nut; and consisting of cells which are branched, roundly oval or round, transparent, colourless; of various sizes, the larger ones termed "giant cells," some of which measure as much as 1/16th inch in diameter. They are simple masses of protoplasm without any limiting membrane, con-
Tubercles are either isolated or grouped together into irregular masses, which sometimes appear as circumscribed excrescences of varying size, and as if consisting of one mass. A careful examination will, however, reveal that each mass consists of an aggregation of groups of tubercles which are more or less confluent. These masses contain vessels which do not belong to the tubercle, but to the part in which it is situated.

Tubercle is incapable of higher development than the grey nodule, and is prone to rapid decay. The retrogressive change commences in the centre of the nodule, and an incomplete caseous material is the product of the death of the cellular elements.

The granulations of tubercle, except at their first development, do not increase as other growths do. They harden by the in-
creasing consistence and number of their corpuscles; and this:
hardening, by depriving them of nutritive material from the
blood, leads to their retrograde metamorphosis. Tubercle in
this caseous condition was formerly looked upon as a distinct
variety, and was called yellow tubercle. When this change has
just commenced, and the granulation presents a greyish-white
margin and a yellowish opaque centre, it presents its most
characteristic features.

Retrogressive changes.—The conversion of the grey tubercle
to the yellow is the most common retrogressive change. The
metamorphosis commences in the centre of the nodules, changing
the granulations from a grey translucent to a yellow opaque
colour, the yellowness of the tubercle depending upon the con-
version of the cell contents into oily material.

In some cases tubercle wastes and dries, without undergoing
the caseous degeneration, assuming a consistence approaching
that of cartilage. This is a much more favourable termination
than caseation. In this cartilaginous mass earthy salts may
subsequently be deposited.

The caseous or yellow tubercle either softens or gradually
dries up into a firm cheesy mass, which ultimately becomes calca-
reous, and the calcareous salts are generally found most abundant
around the circumference or surface of the nodule, enclosing or
encapsuling a softish friable substance, consisting of fat granules,
aggregated globules of oil, pigment masses, and plates of choles-
terine. The tubercle is thus rendered inert, and undergoes no
further change. But before the final drying up and calcification
of the caseous substance, it not infrequently happens that
softening takes place. The caseous mass undergoes a process of
liquefaction, and becomes converted into a curd-like puriform
fluid. If the tubercle is situated on a mucous membrane the
softened matters are eliminated, and an ulcer is formed; if in
the parenchyma of organs, as in the lungs or lymphatic glands,
a pseudo-abscess results.

If the softened matters cannot be eliminated the more fluid
portions are absorbed, and the nodule gradually dries up into a
firm caseous substance, which usually becomes infiltrated with
calcareous particles, and is thus converted into a hard calca-
reous mass.
CHEMICAL COMPOSITION OF TUBERCLE.

Tubercle has been analysed by many chemists. That of the late Dr. R. M. Glover of Newcastle appears to be the most accurate. His conclusions are as follows:—(1.) That tubercle consists of an animal matter mixed with certain earthy salts. (2.) That the relative proportion of these varies in different specimens of tubercle; that animal matter is most abundant in recent, and earthy salts in chronic tubercle. (3.) That the animal matter consists almost entirely of albumen, mixed with a minute quantity of fibrin and fat. (4.) That the earthy salts are principally composed of the insoluble phosphates and carbonates of lime, with a small proportion of the soluble salts of soda. (5.) That very little difference in ultimate composition has been detected between recent tubercle and other albuminous compounds.

CAUSES AND ORIGIN OF TUBERCLE.

Many pathologists are of opinion that tubercle is a new lymphoid growth, resulting from hyperplasia of pre-existent adenoid or glandular tissue. The lymphatic sheaths of the small arteries in many situations are very commonly the seats from which tubercle springs. The cells seem to multiply at separate centres, and miliary nodules are thus produced around the vessel, which, as they increase, gradually compress and ultimately occlude it. In the same way, it may originate from the adenoid tissue of the follicles of the spleen and lymphatic glands, from that which exists in the lungs in the neighbourhood of the minute bronchi, from the small collections of it beneath the epithelium of the pleura and peritoneum, and from that beneath the mucous membrane of the alimentary canal. In other cases the tubercle originates from cells situated within the lymphatic vessels. Many of the tubercular granulations which occur in the pleura and peritoneum are simply overgrowths of minute adenoid tissue, which normally exists in these situations. When tubercle originates from the adenoid tissue surrounding the blood-vessels, and from that in the spleen and lymphatic glands, and in other situations where it exists in the diffuse form, the cell proliferation takes place at several separate centres, so that
numerous granulations are produced which may ultimately become more or less confluent at their margins, and so form large masses. Such being the mode of development, it is evident that the tubercles are structurally inseparable from the tissues in which they grow, the centre of the granulation being surrounded by a zone of proliferating tissue.

Dr. Lionel Beale says that the tubercle-corpuscles, like pus and cancer, is a minute particle of living matter, very distinct, however, from pus, lymph, white blood-corpuscles, and cancer, although perhaps not differing from these in its histological characters, but in its life history. Pus grows much faster than tubercle, and tubercle much faster than cancer. Pus might possibly result from the rapid growth of tubercle or cancer, but neither of these could be derived from pus. Tubercle grows, and the corpuscles move into the portions in which they are found; the oldest die, and caseous matter is one of the products of death.

Dr. C. J. B. Williams again holds an opinion that tubercle is not formed by growth of the adenoid tissue. He says—"For my own part, I had forty-five years ago expressed my conviction that miliary granulations in the lungs owed their constant form and size to their connection with some elementary part of the lung texture, and I was quite prepared to conclude, on the new evidence given, that the lymphatic tissue is that element; but that they are simple overgrowths of that tissue, I could not, and do not admit; nor do I believe that the lymphatic tissue is at all necessary to the production of other tubercular formations which are not granular. A mere overgrowth of a tissue ought to be an increase of all its parts—of the stroma, of the trabeculae, of the lymphatics—as well as of the corpuscles; and this we have in true lymphoma and in the adenoid enlargements of leucæmia. But this is not tubercle. In tubercle you have increase only of the corpuscles, and they are not merely multiplied, they are altered; they are harder, so that, as they crowd in their proliferation, they form, not soft expanding swellings as in lymphoma, but little hard nodules; and their subsequent history of irritation and obstruction of surrounding parts, and of decay and caseation in themselves, is dependent on this character of induration, which is not comprehended in the term overgrowth."

—(Discussion on Tubercle, before the Pathological Society of London, April 1st, 1973.)
Virchow, again, maintains that tubercles are composed of the retrograde metamorphosis of physiological or morbid tissue elements, and he holds that a local process in all cases leads to an exudation of a material which is poured out during what he calls "a tuberculous inflammation," and which becomes organized to a certain extent, and then dies, breaks up, shrivels, and so becomes tubercle. This process he calls "tuberculosis," and the state of the body which gives rise to it he terms "scrofulosis." According to this view, tuberculosis is the local process in which there occurs an exudation of a material, nutritive or pathological, which develops into cells, and that these cells tuberculize or undergo the tuberculous metamorphosis, and in the words of Paget, "the relation between the two [terms] is, that the scrofulous constitution implies a peculiar liability to tuberculous diseases," or, in other words, to caseation, &c. of the products of an inflammation. This view is supported by what is witnessed particularly in horned cattle, namely, the formation of caseous tumours in various parts of the body.—(See page 399.)

Tubercle was held by Laennec and others to be due to the formation of a non-inflammatory material (neoplasm) originating spontaneously in the tissue; and by others, that it was an exudation—a deposit of caseous matter from the blood. These views are now generally abandoned, and it is believed that the growth is inflammatory; that the cause of inflammation may be simultaneously the cause of tubercle; that tubercle owes its origin to the absorption and distribution of an infective material derived from the absorption of the metamorphosed product of the inflammation. Thus Buhl was led to conclude that in the majority of cases of tuberculosis caseous masses existed in some part of the body, and that to the absorption of substances from these infective centres the general development of tubercle was owing. This seems to me to be a proper view to take of the origin of tubercle in the majority of instances in horned cattle; for since the appearance of pleuro-pneumonia tubercular growths are much more frequently met with; but there is sufficient evidence to prove that cattle, more especially the high-bred ones, are constitutionally predisposed to wasting diseases, in the course of which tubercles and other allied formations become developed.

Tubercle again, particularly in cattle, is associated with caseous tumours in some parts of the economy, particularly in the
bronchial glands, and an examination of these in the generality of cases—that is to say, in those instances where the tubercular growths have undergone the calcareous change—will reveal that the morbid product in the bronchial lymphatic glands is of prior origin to the tubercle: more particularly is this condition observed when tubercle is a sequel to catarrhal pneumonia, a disease where invariably, even in its earlier stages, these glands are found enlarged, the whole lymph paths filled with large catarrhal cells, and the endothelial cells, lining the stroma, actively dividing. At a later stage caseation is seen commencing in the centre of the accumulated cells, and this goes on until the whole becomes at first a caseous, and finally a calcareous mass—the secondary growths or tubercles in the lung substance (and these are easily demonstrable from abscesses in the lungs), or in the subserous tissue of the pleura or other serous membrane, being evidently less advanced in the retrograde change.

We cannot, however, look upon tubercular diseases as they occur in horned cattle as belonging to the same category as the phthisis pulmonalis of man—that is, an ulcerative lung disease—in its strictest sense. But similar conditions, both extrinsic and intrinsic, lead to the production and development of a chronic inflammatory disease in these animals, as well as in the pig, more rarely in the sheep, and seldom in the horse, in which we find that suppurations have a greater tendency to the discharge or liquefaction of the pus than in the ox, as shown in ordinary subcutaneous abscesses, which in the horse are generally acute and discharge their contents, whilst in the ox—most subject to the serofulous inflammation of the domesticated animals—they are generally indolent, their contents tending to caseation, similar to tuberculosis in man, and the development of tubercle is undoubtedly a local manifestation of a constitutional peculiarity. Hereditary predisposition has a marked influence upon the development of tubercles. Predisposition, even in man, is, however, held by some to be more of a tendency to chronic inflammations of certain organs, especially of the lungs, mucous membranes, and lymphatic glands, than to the primary development of tubercle; the localized or disseminated tubercular growths being secondary to, and resulting from, the direct irritation or infective properties of the inflammatory products.

According to Dr. Sanderson, three things are necessary for the
establishment of phthisis:—(1.) A constitutional predisposition; (2.) A local irritation, leading to an increased growth of pre-existing lymphoid structures; and (3.) A process of infection, by means of which the morbid growths extend to adjacent or related parts. This view does not, however, meet with universal approbation, and in the opinion of many tubercle may result from bad food, imperfect digestion, or any debilitating operation or influence. Thus, in horned cattle, it is found that the best milkers are most prone to "pining," or consumption. Improper food or an unhealthy digestion give rise to disease by diminishing the quantity or deteriorating the quality of the elements of nutrition.

It is also observed that excessive acidity exists in the alimentary canal in phthisis. This excess of acid is said to render the albuminous constituents of the food easily soluble, whilst the alkaline properties of the saliva and pancreatic juice are more than neutralized, and rendered incapable either of transforming the starchy constituents of vegetable food into sugar, or of so preparing fatty matters introduced into the system as to render them easily assimilable. Hence an increased amount of albumen enters the blood, and has been found to exist there by all chemical analyses, while fat is largely supplied by the absorption of the adipose tissues of the body, causing the emaciation which characterises the disease. In deep milkers the deficiency of fatty materials in the blood may be simply due to their rapid removal from the body by the mammary gland; and in addition to the influence of this direct drain upon the system, a state of chronic indigestion often exists from improper feeding, want of exercise, and from being kept in a continual artificial state.

**ARTIFICIAL PRODUCTION OF TUBERCLE.**

Villemin, Burdon Sanderson, Wilson Fox, Cohnheim, Klebs, and others found that by inoculating guinea-pigs and rabbits with tuberculous or chronic inflammatory products under the skin, small indurated caseous nodules became developed at the seat of operation; that the next lymphatic glands had undergone hyperplastic enlargement, and that the lungs, liver, serous membranes, and other organs presented a greater or less number of small, grey, translucent, hard bodies, identical with miliary tubercles, and that the organs so affected increased in bulk and
weight to an abnormal degree. Hence it was concluded that tubercle could be propagated by inoculation; but further experiments have gone to show that the same internal lesions may be induced by the introduction of other forms of growths, of decomposing healthy tissue, or of the products of local inflammations, or by the introduction of an ordinary irritant, such as a seton beneath the skin, and thus it was found that there was nothing very specific about it. Again, if a guinea-pig be inoculated with pus, if it does not die from acute pyæmia shortly after its inoculation, it is found that tubercular-like masses become developed in various organs of the body; hence it is concluded that the rodentia, and particularly guinea-pigs, are very peculiar creatures. Professor Bennett failed to propagate tubercle by inoculation in the rabbit.

The experiments of Sanderson and others have, however, proved that, in some animals at least, tubercle can be artificially induced by exciting a simple local inflammation of the skin and subcutaneous tissues. These throw much light upon the occurrence of tubercular growths as sequæ of inflammations, and as it is proved that the exudate of a local inflammation in guinea-pigs tends to become caseous, it is fair to conclude that the same tendency exists in cattle, which are most prone of our patients to tubercular disease, in the lymph of pleuro or broncho pneumonia, thus proving the conclusions of Buhl, “that tubercle in the majority of cases was due to the absorption of caseous matter.”

Koch, however, boldly maintained that tubercle is a purely contagious disease, arising from the invasion of a microbe—the tubercular bacillus—a very minute and delicate shaped rod, and, unlike other bacilli, unstainable by methylaniline blue, but taking on the magenta colour, which, when combined with methylaniline blue, gives a double staining—the tubercle bacilli taking up the magenta, whilst other microbes present are stained blue.

The aim of Koch has been to determine the precise character of the contagium which previous experiments in inoculation and inhalation had proved to be capable of indefinite transfer and reproduction. He subjected the diseased organs of a great number of men and animals to microscopic examination, and found, in all cases, the tubercles infested with a minute rod-shaped parasite, which, by means of a special dye, he differentiated from the surrounding tissue. It was, he says, in the
highest degree impressive to observe in the centre of the tubercle cell the minute organism which had created it. Transferring directly, by inoculation, the tuberculous matter from diseased animals to healthy ones, he in every instance reproduced the disease. To meet the objection that it was not the parasite itself, but some virus in which it was embedded in the diseased organ, that was the real contagium, he cultivated his bacilli artificially, for long periods of time and through many successive generations. With a speck of matter, for example, from a tuberculous human lung, he infected a substance prepared, after much trial, by himself, with the view of affording nutriment to the parasite. Here he permitted it to grow and multiply. From this new generation he took a minute sample and infected therewith fresh nutritive matter, thus producing another brood. Generation after generation of bacilli were developed in this way, without the intervention of disease. At the end of the process, which sometimes embraced successive cultivations extending over half a year, the purified bacilli were introduced into the circulation of healthy animals of various kinds. In every case inoculation was followed by the reproduction and spread of the parasite and the generation of the original disease. Of six guinea-pigs, all in good health, four were inoculated with bacilli, derived originally from a human lung, which in fifty-four days had produced five successive generations. Two of the six animals were not inoculated! In every one of the inoculated cases the guinea-pig sickened and lost flesh. After thirty-two days one of them died, and after thirty-five days the remaining five were killed and examined. In the guinea-pig that died, and in the three remaining infected ones, strongly pronounced tubercular disease had set in. Spleen, liver, and lungs were found filled with tubercles, while in the two uninoculated animals no trace of the disease was observed. In a second experiment six out of eight guinea-pigs were inoculated with cultivated bacilli, derived originally from the tuberculous lung of a monkey, bred and rebred for ninety-five days, until eight generations had been produced. Every one of these animals was attacked, while the two uninoculated guinea-pigs remained perfectly healthy. Similar experiments were made with cats, rabbits, rats, mice, and other animals, and, without exception, it was found that the injection of the parasite into the animal system was followed by decided,
and in most cases virulent, tubercular disease. In a vast number of cases Koch has examined the matter expectorated from the lungs of persons affected with phthisis, and found in it swarms of bacilli, while in matter expectorated from the lungs of persons not thus afflicted he has never found the organism. The expectorated matter in the former cases was highly infective, nor did drying destroy its virulence. Koch points to the grave danger of inhaling air in which particles of the dried sputa of consumptive patients mingle with dust of other kinds.

Whilst the observations and experiments of Koch strongly support the opinions of many pathologists, that each specific infective or contagious disease is due to a special or pathogenic germ, organism, or bacterium, they also prove that infective disease can be created by the cultivation of these molecules of matter continually floating in the air, waiting as it were for a proper pabulum in which they may propagate and develop.

The experiments of Davaine, Ceze, Feltz, Sanderson, and many others went to prove that septicemia from the injection of putrid blood could be induced in rabbits. Koch, however, did not succeed in so inducing it, but obtained a result which had been observed by others, that an abscess, which constantly increased in extent, occurred in the subcutaneous tissue without any general infection.

Such rabbits at first show no signs of disease; a flat, hard swelling at the seat of the injection is all that can be observed. After several days this hardness extends in all directions, but chiefly downwards, the animal at the same time losing flesh, becoming feeble, and dying in from twelve to fifteen days after the injection.

The post mortem examination shows that these flat abscesses have cheesy contents, and that their walls bulge in various directions. The emaciation is extreme, but no disease is found in the peritoneum, kidneys, spleen, liver, heart, or lungs; the white corpuscles of the blood are greatly increased, but no bacteria can be found in the blood or even in the contents of the abscesses; but the abscess walls are filled—Koch says formed—by a thin layer of micrococci united together into thick zoogloeous masses. These are the smallest pathogenic micrococci as yet observed.

The injection of healthy rabbits with the blood of those which had died of the induced disease produced no effect, but when a
small quantity of the cheesy contents of the abscess was taken,
diluted with distilled water, and injected under the skin of a
rabbit, the result was exactly the same abscess formation as
when the injection was made with putrefying blood.

Experiments with putrefying blood prove that at least four
diseases, three of which are highly infective, can be induced
by agents which abundantly surround us:—first, death from the
toxic effects of sepsin; second, septicæmia, with the develop-
ment of infective bacteria; third, gangrene of the tissue, from
the invasion of micrococci, surrounding the inoculated spot; and
fourth, the resistance to septicæmia by the rabbit, but the in-
duction in this animal of an infective caseous disease,—in fact, of
tubercle.

Whilst maintaining my opinion that tubercle is endogenous,
and due to the absorption of the caseous product of a preceding
inflammation, and that the experiments to prove its contagious-
ness and even infectiousness do not go beyond this, namely,
the introduction of degenerated products of disease into the
body of a healthy animal; I feel bound to state that many
experiments have been made, some proving the contagiousness
and infectiousness of tubercle, and some disproving its specific
or infecting qualities; and the experiments of Villemin, Chauveau,
Klebs, Gerlach, Bagge, Semmer, Gunther and Harms, Zürn,
Dithi, and Vergad may be arranged, according to Bollinger, under
the following heads:—

1. Ingestion of tubercular matter derived from man. In two
pigs and two rabbits, a negative result. In one pig, enlargement
of Peyer's patches and mesenteric glands, and cheesy degenera-
tion of parts of these.

2. Ingestion of tubercular matter from the ox; fresh glands,
caseous matter, the contents of the bronchi. Animals experi-
mented upon:—Five sheep, two goats, four pigs, eight dogs, a
large number of cats, twenty rabbits, one porpoise, eight pigeons.
A negative result with the dogs and cats; result nearly always
positive with the pigs, sheep, and goats. Most frequently with
these animals there was caseous degeneration of the intestinal
mucous membrane, mesenteric glands, sometimes the cervical
glands, and the lungs. In three sheep there was real "tabes
mesenterica." With the rabbits, the ingestion of raw tubercular
matter produced results sometimes positive, sometimes negative.
In one instance, the ingestion of boiled tuberculous lymphatic glands engendered general tuberculosis; but, on the other hand, boiled tubercles had no injurious effect on five rabbits; and a pig, fed with the same material, only exhibited after death tumefaction of the mesenteric glands. Cooked or uncooked tubercles, given to other rabbits, infected them; and the ingestion of tubercles from an ox infected a porpoise, but had no action on two pigeons. The ingestion of caseous pus alone had no effect on a sheep.

3. Ingestion of flesh from tuberculous oxen, or those artificially infected. Positive result in three pigs: general tuberculosis or alterations in the lymphatic glands. In one pig, leucæmia, scrofula, and tuberculosis. Result always negative with rabbits when fed with raw or cooked flesh.

4. Ingestion of the milk of a tuberculous cow. Three pigs, three calves, one sheep, two goats, two cats, and fourteen rabbits. In the three pigs, mililiary tuberculosis, and lesions analogous to those of scrofula; in the two cats, a negative result; a positive result in two rabbits; a negative result in fourteen rabbits fed with the boiled milk.

Bollinger thinks it possible, or rather probable, that intestinal tuberculosis, consecutive to pulmonary phthisis, may be produced by the sputa swallowed passing into the intestine. He also thinks it demonstrated that scrofula and tuberculosis are only two forms of the same disease, at different periods of development.

Experiments have also been made with the view of proving the transmissibility of tubercle, not only by inoculation and ingestion, but by infection through the medium of the breath of fine particles of tubercular sputa. The animals experimented upon were compelled to breathe for several hours daily in a chamber, in the air of which were fine particles of phthisical expectoration from persons with cavities in their lungs, mixed with water, and rendered into fine particles by a steam atomiser. Dogs alone were experimented upon, as they rarely suffer from tubercle. Eleven animals were experimented upon, and all were killed in a period varying from twenty-five to forty-five days, and, with one doubtful exception, presented well developed mililiary tubercles in both lungs, and in most of them tubercles were also found, but to a smaller extent, in the kidneys, and to a smaller extent in the liver and spleen. Microscopical examination was in accordance with the naked eye appearances.
These experiments were conducted by Dr. Tappeiner of Meran, and a preliminary account of them led Dr. Max Schottelius to make similar ones, not only with the sputum of phthisical individuals, but also with that of persons suffering from simple bronchitis, and with pulverised cheese, brain, and cinnabar. The result was that miliary tubercles were found in the lung in all cases, and in equal quantity with both phthisical and bronchial sputum. Cheese produced a smaller quantity, pulverised brain still less, and the cinnabar least of all, merely a few whitish tubercles with pigmented centres, with an interstitial deposit of the substance which had caused no inflammatory reaction. Tappeiner has also experimented with calves’ brain in two cases, but with purely negative results. No changes in the lung followed such as resulted from the inhalation of tuberculous sputum.

“The experiments,” says the editor of the Lancet, November 23, 1878, “are of much interest, but they need a repetition on a large scale, in order that the discrepancies may be removed, before much weight can be attached to them as evidence of a specific influence of phthisical sputum. They unquestionably show, however, that the inhalation of foreign organic matter will cause tubercles in animals naturally predisposed to their development. The appearance of granulations in other organs than the lungs, in some of Tappeiner’s experiments, is a fact of great importance.

“Whether tuberculous matter produces tubercle when given in this manner more readily than other substances, or not, it appears certain that the inhalation of these substances is more effective than their administration by the alimentary canal. These facts are of great importance in regard to the question of the contagiousness of phthisis.”

DIVISIONS.

Tubercular diseases as they occur in cattle may be classified under three heads:—1st. Tubercular Dysentery; 2d. Granular Inflammation; 3d. Scrofulous Infiltration of Glands.

1st. Tubercular or Chronic Dysentery.—The only common ulcerative disease which has its origin in tubercle. Phthisis pulmonalis, or ulcerative lung disease, rarely exists in the
bovine tribe. In this, as well as in its homologue in man, the lower parts of the intestines are the seat of the growth and ulceration. In chronic dysentery the tubercle grows in the submucous tissue, and elevates the mucous membrane over the granulations. The growths degenerate and soften; new granulations spring up between the degraded ones; these also degenerate and soften, and a fusion of the whole very soon takes place. The circulation is impeded, the mucous membrane is removed, and deep pit-like ulcers form, which by coalescence become large, with irregularly excavated borders. The borders of these ulcers are thick, and are impregnated with yellow, degraded tubercular matter, and in some cases the ulcers penetrate the intestinal walls.

2d. Granular Inflammation.—Of this there are two kinds, namely—(A.) Caseous and Calcareous Tumours, non-recognisable prior to death; and (B.) Tuberculosis of Lungs, Serous Membranes, and Glands, preceded or accompanied by wasting, debility, a general mal-condition of the body, and elevation of temperature.

(A.) Caseous Tumours.—If the history of cattle, slaughtered sometimes in the primest condition, in which these tumours are found could be traced, it would in all probability be discovered that at some prior period they had suffered from capillary bronchitis, pleuro-pneumonia contagious, or other inflammatory disease. In many instances this has been done, but it is impossible in all cases, as cattle are often changing owners. It is, however, fair to assume that such is the case, and we are warranted in the assumption by actual facts which have been observed. Within my own experience I have known numbers of cattle recover from pleuro-pneumonia, and regain the best of apparent health, but in whose bodies, after slaughter for human food, immense circumscribed tumours, or masses of so-called tubercular matter, have been found in the lungs, pleura, peritoneum, sides of the diaphragm, and in various glands, mesenteric, liver, kidneys, &c. These masses, called “angle berries or grapes” by butchers, vary in size from that of a small pea to a hen’s egg or larger. They are often confluent, and one apparent mass sometimes weighs many pounds, whilst in the aggregate they may weigh many stones. When cut into they are invariably found to consist of caseous material intermixed with calcareous matter. Microscopically
examined, they are seen to be made up of shrivelled cell elements, oil globules, cholesterine, and lime salts.

The flesh of such animals is very often of a fair or even superior description, and the only question of importance in connection with the matter is, whether the flesh is fit for human food. This question is asked, because very often such flesh is condemned by market inspectors. If, however, we can only train our mind to consider that these masses are mere growths—that in fact they are no more injurious to the quality of the flesh than warts or other excrescences on the skin—the feeling of fear may be overcome. I am of opinion that these excrescences are mere results of a previous and perhaps distant inflammation; that the products of such inflammation are thus localised, whereby they are prevented from injuring the general economy; that in fact they are as much external to the general economy of the animal as so many excrescences in the skin, or tumours in any part of the body, and that if they are carefully removed, and the membranes and structures in which they are embedded and from which they grow carefully dissected out, the flesh is perfectly good, fit for any man's table, and that it is a pity to destroy valuable and nutritious human food because the term tuberculosis has been applied to the tumours.

(B.) Granular inflammation arising from cachexia or blood crisis.—The cachexia, inherited or arising from the absorption of the products of an inflammation, may precede the formation of the granula, or may result from softening of them, and the absorption of the softened products. In the latter case signs of ill health appear, excited perhaps by parturition, a slight cold, indigestion, or some other, perhaps trivial, cause; the illness continuing longer than usual, and the animal being fat and in good condition, is slaughtered to prevent loss, and the post mortem reveals the presence of the above described tumours. In this case some of the tumours will be found in a softened, semi-fluid condition, to the absorption of which the continuance or aggravation of the trivial illness is due; thus the whole body becomes empoisoned and the flesh unfit for human food. The various structures of the body will be found pale, watery, pitting under pressure, and prone to rapid decomposition.

In deep milkers, and in some highly bred cattle, the cachexia may precede and accompany the tuberculosis, and generally the
earliest signs are those of unthriftiness, and deterioration in the quantity of the milk, which becomes thin and watery, although for some time it may keep up in quantity. If the cow be in calf abortion is apt to occur; if not pregnant, the condition called nymphomania is frequently present. The appetite is capricious; the mucous membranes pale; a dry cough of a dull character exists; the skin looks dull, the hair dirty; the animal does not lick itself, and, in the white parts, the skin is often observed to be yellow. Emaciation now proceeds more or less rapidly; the cough becomes troublesome, but there is no expectoration or discharge from the lungs. The digestive organs are weak, the rumen prone to tympanitis, and diarrhoea sets in, which soon renders the animal a mere bag of bones. Auscultation and percussion may find the lungs and contents of the thorax diseased or otherwise. There is generally some degree of pain and tenderness evinced by the animal when the sides are sharply struck or pressed upon, and very often a friction (pleural) sound is heard. In many cases the thoracic cavity becomes more or less filled with fluid, and the abdomen enlarges from ascites. These are uncertain combinations, and a post mortem may reveal the tubercular matter on the mediastinum, pericardium, peritoneum, in the mesenteric glands, or in all of them. When the tubercle is found in the mesenteric glands the term “tabes mesenterica” has been applied to the disease.

This form of “wasting,” “consumption,” or “pining”—terms by which the disease is known in various parts of the country—is very often hereditary, and I have frequently seen it commit havoc amongst many herds, in the breeding of which no attention had been paid to stoutness as well as beauty of conformation.

It is not only hereditary but congenital, and I have seen a calf three months old, which had thriven well until within two or three days of its death, filled with caseous, calcareous, and grey tubercular tumours. In this calf the whole of the serous membranes were affected, the pleura and peritoneum covered by calcareous and caseous tumours, which must have been formed in utero, and the arachnoid, with tubercle in its early stage of development, presenting in a most remarkable manner the appearance figured in (a.) fig. 15, page 407. The large lymphoid
cells were very numerous and very distinct. The mother of this calf seemed a healthy animal, but was of a spare form, and had a capricious appetite.

Another calf, in a condition very similar, was sent to me by Mr. Borthwick, Kirkliston, in which the internal changes were analogous.

3d. Scrofulous infiltration of Glands, or Tubercle with external manifestations.—The formation of tubercular or scrofulous tumours is not an infrequent manifestation of the tubercular diathesis, not only in well-bred cattle and deep milkers, but in the hill cattle of many districts, and particularly amongst those reared upon heavy clays and undrained lands. In Scotland these tumours are commonly called “clyers” or “cruels,” and present themselves as hard tumours in the parotid or submaxillary regions, appearing at first as round, movable nodules, which gradually enlarge, and finally become adherent to the skin, which inflames and finally ulcerates, leaving a raw unhealthy ulcer, from which an ichorous or sanguineous discharge continues to issue. Abscesses sometimes form in these regions; these must not, however, be confounded with scrofulous ulcers. The true abscess suppurates, bursts, and heals up again. The scrofulous ulcer has no tendency to heal, but rather to spread, and in many cases multiple ulcers will form in the enlarged glandular mass. As the tumours increase in size—and this increase occurs whether ulceration is established or not—the pharynx and larynx are often pressed upon, and breathing and deglutition become difficult.

Tubercular arthritis.—In herds predisposed to tubercle, it will be often witnessed that some of them become lame from no assignable cause. The lameness is generally irremovable, and post mortem examination reveals that it has been due to tubercular inflammation of a joint or joints. It is well to keep this in remembrance, as many cattle have been sorely tortured by attempts to remove by violent remedies—such as firing, blistering, &c.—what from its nature is irremovable. The history of the herd, and of its tendency to tubercle, will enable the practitioner to pronounce upon the nature of the lameness, and to prescribe a rational course of treatment.—(See Principles and Practice of Veterinary Surgery, page 231.)
In the horse tuberculosis is very rarely witnessed, the growths sometimes supposed to be tubercular being lymphomatous formations, which differ from tubercle in having little or no tendency to caseation.

TREATMENT.

If the disease has passed beyond the very earliest stage, it is a waste of time and money to treat animals suffering from tubercular consumption. It is far better to slaughter, and make the best of them; and in all cases it is better to make the animals fit for the butcher by ceasing to milk them, giving fattening food, such as oil-cake and good hay, avoiding grasses and roots, as they tend to produce indigestion, diarrhœa, and an acid condition of the digestive apparatus, and by administering cod liver oil in such quantities as the animal may digest and assimilate—say from six ounces to half a pint daily; if purgation is not induced, the latter quantity. The oil is best given mixed with lime water, and small doses of oil of turpentine may also be added with advantage, particularly if there be a tendency to indigestion, tympanitis, or diarrhœa.

I think, however, the time has arrived when tubercular diseases ought to be included in the Contagious Diseases (Animals) Act, and that an endeavour should be made to prevent its increasing frequency, even if it be found impossible to diminish it, or stamp it out altogether.

It must be particularly borne in mind by the veterinarian that, as a conservator of public health, he should at all times discountenance the consumption of the milk of tubercular cattle, not only by human beings, but by the lower animals, for it has been abundantly proved (see page 418, paragraph 4) that the milk of a tubercular cow may be dangerous to human life; and when we reflect upon the fact that it is so largely consumed, particularly by infants and young children, we can at least imagine the appalling consequences it may give rise to.

The danger to human life from the ingestion of the milk of a tubercular cow is greatly increased if the mammary gland be in a condition of inflammation, the seat of an abscess, or in a state of induration, as—in addition to the deficient nutritive value of
all milk from tubercular cows, which is blue in colour, thin in consistency, and in some cases contains cyanides—it will in such an instance be tainted with true tubercular matter in the form of cells and bacilli, and be a direct means of infecting the human being, particularly young and delicate infants. Let the veterinary surgeon, when called upon to give his opinion, consider the sacredness of his position, and—even if he chance to offend a client—do his duty towards his fellow-beings.

The majority of the veterinary profession are in favour of preventing the flesh of all tubercular cattle—no matter what its condition and appearance may be—being used as human food; but, for the reasons stated on page 421, I cannot support the wholesale condemnation of such flesh as human food. But whilst maintaining such flesh is fit for food, I must explain that if it presented any appearance of being watery, pale, or otherwise unhealthy, I should not hesitate in at once expressing my conviction that it should not be used as food for man.

*Treatment of septiculous glands.*—Avoid all irritants in the shape of blisters, iodine, or caustics of every description. If ulceration is established, dress with charcoal, or a mixture of carbolic acid and chalk, and feed the animal for the butcher, if not too late, as quickly as possible give cod liver oil, and an occasional ferruginous tonic. If the breathing is impeded, tracheotomy may be performed, provided the appetite be good and deglutition easily performed; but if the appetite is capricious, deglutition performed with difficulty, or if there be signs of wasting or "pining," or a tendency to diarrhoea, the first loss is the better.

**Strumous Abscesses.**

In the *Provisional Nomenclature of Diseases* adopted by the Royal College of Physicians, London, tubercular diseases are considered under two heads, namely—(1.) Scrofula with tubercle; and (2.) Scrofula without tubercle. This latter condition is witnessed in the sheep, in which the tubercular nodule is rarely spontaneously developed. This ruminant, however, is prone to suffer from a condition similar to that which leads to the growth of tubercle in the ox and other animals, and in
which strumons or scrofulous abscesses, commencing in the connective tissue about the jaws, neck, and face, or as results of inflammation of the lymphatic glands (strumous adenitis) of the submaxillary space are developed.

These abscesses often appear, without any premonitory signs of ill health, as hard swellings, which sooner or later suppurate imperfectly, or burrow deeply in all directions; at first they are not painful, but often become very much so, and may multiply rapidly, appearing between the jaws, on the neck, about the eyes, lips, and nostrils, and occasionally upon other parts of the body, causing swelling, preventing the sheep from feeding, and rendering the breathing difficult and snoring. In some instances swelling of the face and discharge from the nose are observed previous to the development of the tumours.

Young animals, particularly young fast-growing rams, if exposed to cold, are especially subject to this disease, but older animals of both sexes, as well as lambs, are not exempt.

If these abscesses are opened, the quantity of pus contained within them, not always commensurate with their size, is generally thick, and flows tardily, but afterwards becomes thin, and more or less ichorous; it is surrounded by a thick sac of low fibrous material, like the walls of an old ulcer, and sinuses are often found running from the cysts into the surrounding structures. Microscopically examined, the pus is found to consist of ordinary pus cells, rather shrivelled in appearance, but showing no tendency to caseation. In many instances the tumours undergo little or no change for two or three years, the sheep seemingly suffering no inconvenience; but in other cases the animal loses flesh rapidly, the wool falls off in patches, symptoms of fever manifest themselves, a cough is now and then heard, and the sufferer dies from exhaustion, anaemia, and sometimes dropsy. The flesh in this advanced stage is pale and watery, but if an animal be slaughtered in the earlier stages, it is fairly good.

The post mortem appearances are often quite local, merely collections of pus in the various thick-walled abscesses observable before death; the pus will, however, be found to have burrowed from the abscesses in various directions into the surrounding tissues. Now and then some degree of ulceration of the nasal mucous membrane may be detected, and abscesses found in
the lungs, but these two latter conditions are by no means constant.

Strumous abscesses in sheep, or the conditions which lead to their formation, do not seem to be hereditary, as the stock of many tups affected with them remain quite free from the disease, provided they are not exposed to that cause—namely, cold—which induces it in the progeny of those which have never been affected.

Treatment.—The cause or causes being removed, it will be necessary to open the abscesses as soon as pus can be detected in them, a matter of some difficulty, as their walls are very firm and unyielding; however, if by firm pressure with one hand, and manipulation of the tumour with the other, the pus can be felt fluctuating slightly, the operator need not hesitate, but make a bold incision, press out the semi-fluid matter, and dress the wound with some digestive, such as turpentine liniment. The parts are to be kept clean, dressed daily, the wounds prevented from closing too quickly, and the animal fed liberally. A small quantity of sulphate of iron in the food often assists the recovery. A varying degree of swelling may exist for a time after the wounds have healed.
CHAPTER XXXVI.

SPORADIC DISEASES—continued.

(II.) DIETETIC DISEASES.

In order that the health of the animal body may be duly maintained, it is necessary that the various kinds of food should be sufficient in quantity and undeteriorated in quality. It is also necessary that the food contain at least three classes of constituents, each of which plays an important part in supplying the various wants of the economy. These constituents are—(1.) Nitrogen, which seems most fitted to nourish muscular and other albuminoid tissues; on this account the substance containing it has been called plastic or nitrogenous food. Substances defective in nitrogen, and having an excess of carbon or hydrogen, are called (2.) hydrocarbons; these supply materials which undergo combustion in the body, and assist in maintaining animal heat. If this hydrocarbonous or respiratory element also contain fat, it assists in maintaining the animal heat, and in the assimilation of the nitrogenous compounds. Food must also contain (3.) saline materials, in order that the solid structures of the body be built and maintained in health; the saline constituents also aid in the processes of assimilation and elimination, of carrying new materials into the system and old materials out of it. If these constituents are absent, or are present in undue proportions, health cannot be maintained, and common experience has taught us that all animals are kept in the best health when fed on a mixture of food.

Although chemical analyses have enabled us to know the quantities of nitrogen, carbon, &c. contained in the food, it does not follow (as General Fitzwygram justly remarks) "that the food which possesses these constituents in the greatest abundance
will produce the most beneficial results. Digestibility, readiness of assimilation, absence of unduly heating properties, and many other qualities, are needed in order to make a substance possessing the necessary ingredients available as food. Chemistry is a valuable but not an infallible guide, and its indications require to be tempered by the test of experience."

Professor Dick said that a horse may be kept without work, but taking a little exercise, in fair condition on 12 lbs. of hay and 5 lbs. of oats per day; but if a good amount of work is to be got out of it, the horse should have 14 lbs. hay, 12 lbs. oats, and 2 lbs. beans. In this diet of the horse at rest there are 29·2 ounces of flesh-formers, and 150 ounces of heat-givers and fat-makers; and in the work diet there are 251 ounces of hydrocarbons, and 59·1 ounce of nitrogenous constituents.

It is not my intention to enter into a lengthy discussion on the above subject. My experience leads me to conclude that the scale laid down by Professor Dick is too limited; that it is necessary to give to a horse at rest several pounds more corn per day in order to keep it in good health. Every-day experience teaches us that no horse can be kept in health without exercise, and no horse taking sufficient exercise to keep it in health can maintain its vigour and flesh on 5 lbs. of oats per day.

I am also of opinion that all horses at work should have a mixture of oats, beans, and hay; say 14 lbs. oats, and 2 lbs. to 4 lbs. of beans per day. I find this to be the cheapest and best of food. It must be given either whole or crushed, dry, and it is advantageous to mix it with chopped hay. The quantity, however, must vary with the size of the animal.

The corn and hay must also be of good quality, sweet, free from mildew, well harvested, old, and dry.

For further information on the subject of feeding, the reader is referred to Sellar and Stephen’s Physiology at the Farm; General Sir F. Fitzwygram’s Horses and Stables; Low, Playfair, Voelcker, and others.

Effects of over-feeding.—Too much hydrocarbonous food favours the development of fatness and obesity. This is well seen in pet dogs and cats fed on cream, sugar, and tit-bits of various kinds. These animals die before half their days are over from fatty infiltration and degeneration of the heart, liver, and other organs. Lions, tigers, and other carnivora kept in menageries
also suffer and die from fatty degenerations, and old carriage and other favourite horses die from the same cause, when pampered and fed with carbonaceous food.

Accumulations of the flesh-forming or nitrogenous elements in the blood, and their non-elimination, cause the development of many blood diseases, as has been already, and will be further shown. For example, over-feeding on linseed cake induces a septic condition of the blood. Analyses of oil-cake have shown that it contains over 22 per cent. of nitrogenous materials, whilst dried wheat contains only 12·47 per cent. of albuminous compounds. Again, decorticated cotton cake contains a much larger per-centige of flesh-forming matters than even linseed cake, and the proportion of oil is higher than in the best linseed cake. The following are the analyses of the two cakes:

The nitrogen of the food is not all assimilated in the system, and a large portion passes away with the excreta; on this account the dung produced by cake-fed stock is particularly valuable. Should anything occur to interfere with the functions of the excretory organs, the nitrogenous compounds accumulate in the system, and there set up a variety of diseases more or less grave and important. It will thus be seen that great care and discrimination are to be exercised in feeding stock upon highly nutritious food; and provided the feeder has an eye more to the maintenance of the health of his stock than to the richness of his manure, he will bear this in mind.

Whilst over-feeding leads to the development of disease, deficiency of food leads to no less grave results; and this
deficiency may relate both to quantity and quality. "A deficiency of food," says Dr. Lethby, "especially of the nitrogenous part, quickly leads to the breaking up of the animal frame. Plague, pestilence, and famine are associated with each other in the public mind, and the records of every country show how closely they are related." It is stated that in cases of very gradual starvation an urgent feeling of hunger is not a prominent symptom, and even when it exists at first, it usually soon diminishes, and is succeeded by a feeling of exhaustion and faintness, and even a loathing of food, if abstinence has been long protracted.

—(R. B. Holland.)

Whilst it is essential to health that food should be sufficient, but not over-abundant in quantity, and that its quality should be so regulated as to supply all the wants of the economy, it must be confessed that the lower animals will live for a very long period on very common fare, provided it be sufficient in quantity, and they are not exposed to extreme cold; but to have health, energy, and condition, both food and water must be good in quality.

A dietetic disease may be defined to be a morbid condition of the body, brought about by food or water deteriorated in quality, insufficient or over-abundant in quantity, or containing some ingredient directly poisonous or injurious to the animal economy.
CHAPTER XXXVII.

SPORADIC DISEASES—continued.

(II.) DIETETIC DISEASES—continued.

(a.) DIABETES INSIPIDUS, POLYURIA, HYDRURIA—
(b.) AZOTURIA—(c.) OXALURIA—(d.) RED WATER
—(e.) ASTHMA, BROKEN WIND.

(a.) DIABETES INSIPIDUS, POLYURIA, HYDRURIA.

A disease characterised by great thirst, excessive discharge of urine, rapid emaciation, languor, and debility. In the majority of instances it is caused by deteriorated food, but in some cases it seems to be due to some constitutional cause, produced through derangement of the assimilative functions, either in the digestive canal, the solid organs, or the blood. When induced by no traceable cause, and where change of diet has no effect in checking it, the disease is generally premonitory to farcy or glands, and is symptomatic of a breaking up of the tissues of the body.

Etiology.—Diabetes is induced by two kinds of causes, namely, intrinsic and extrinsic. The intrinsic causes are those originating in defective assimilation, or rapid tissue metamorphosis, owing to the actual presence of the glands poison, or to a condition of the system tending to its development; the polyuria being induced by the action upon the kidneys of those constituents, products of tissue change, which are naturally eliminated by them. In some instances diabetes results from indigestion, disappearing when the digestive apparatus is restored to its normal condition. It also accompanies other diseases where the digestive process is defective.

The extrinsic causes are to be found in the food which the animal consumes; I am not aware that it is ever induced by the water it drinks. Dark-coloured, highly-heated hay generally
causes much thirst and diuresis, probably containing some ingredient which acts as a stimulant to the kidneys, but it does not induce diabetes so readily as hay that is musty, oats or beans which have been musty or damp, even if kiln-dried, and bran having a peculiar greasy odour, more especially foreign bran.

Diabetes sometimes occurs as an enzootic disease—not due to any atmospheric influence, but following a bad harvest, and caused by damaged food. All writers agree in condemning kiln-dried oats. I am of opinion that these, if of fair quality when put on the kiln, are not so hurtful as is generally supposed, and that they are much more likely to cause disease if given when damp or musty.

In a stud of horses where glanders prevails, the slightest error in feeding the apparently healthy animals will often bring on profuse diuresis. In one stud under my care, a supper of warm boiled food was sure to be succeeded by several animals being attacked by inordinate thirst and diuresis. Habitual feeding on boiled food is a very common cause, and although animals so fed may look moderately sleek, and lay on fat, they are incapable of performing the same amount of work as others fed on similar food given uncooked.

Semiology and Pathology.—The diagnostic signs are excessive thirst and profuse urination: in addition to these there is failing of the appetite. Some teachers say the appetite is increased; I have never known this in the horse, but in the dog there is often a craving for flesh. The visible mucous membranes are pale or sometimes rusty yellow; the skin is harsh and the coat unhealthy looking; the animal is debilitated and rapidly loses flesh. The pulse is often slower than natural, sometimes quicker, and always atonic. The mouth has a sour odour; the horse prefers unclean food and water, and is fond of licking the walls and manger. The urine is of a very pale colour, sometimes as clear as clean water, and has a specific gravity little higher than distilled water, the specific gravity of which is 100, whilst that of diabetic urine is from 100·2 to 100·3, and that of healthy urine in the horse ranges from 100·30 to 100·50. According to Lassaigne, the diabetic urine of the horse contains—water 98·0; urea, benzoate of soda, acetate of potash, acetate of lime, chloride of sodium, and free acetic acid, 1·5; mucus and sulphate of lime, 0·5; and differs from healthy urine.
in (1.) being more watery; (2.) containing acetic acid, and in being free from earthy carbonates.

The diabetes mellitus differs from the insipidus, from the circumstance that the urine contains sugar. I am not aware that this form is ever seen in the herbivora; but I have repeatedly met with it in dogs, and in almost every instance the creatures had been fed for a length of time on boiled liver. M. U. Leblanc reports a case in a dog and another in a monkey.—(See GAMEER’S Domestic Animals.)

Therapeutics.—Investigate carefully the quality and quantity of the food, which in all cases, whether it be apparently good or indifferent, ought to be changed. If the horse is fed on oats and hay, try a change to beans and a fresh sample of hay; if fed mostly on beans, change to oats. The bran and other fodder must also be changed, as any of these articles may contain some undetectable material which operates unfavourably on the economy, some constituent which acts as a constant irritant upon the body and kidneys. It is advisable to give an aperient, and to restrict the diet to hay and mashes for some days. Much relief will be afforded to the animal by giving the bicarbonate of soda in the food or water. I prefer this to chalk, a remedy held in well-deserved esteem.

When the aperient has operated, iodine is to be administered, commencing with two-drachm doses twice a day, and diminishing the dose as the thirst disappears.

Iodine was first prescribed for diabetes by Professor Dick, who discovered, whilst experimenting with it in the treatment of glanders, that it had the effect of allaying the sense of thirst in a most remarkable manner, and ever since then it has been held to possess specific powers in this affection. There is no doubt whatever as to its therapeutic value, for not only does the thirst diminish, but the appetite improves, and all the other symptoms disappear as soon as the system is charged with the iodine.

It is usual to mix clay with the horse’s drinking water; if soda bicarbonate is prescribed, there is no need to give dirty when clean water can be obtained, and it is cruel to restrict the water in quantity to any great extent. The horse must rest, and be carefully attended to for several days.

In the dog the disease is fatal. I have tried various remedies, such as feeding on milk or on flesh entirely; creosote, opium,
Astringents, the bromide of potassium, as well as the iodine treatment, and have seen no permanent benefit from any of them. Both iodine, or iodide of potassium, and the bromide moderate the symptoms for a time, but usually the benefit has been of short duration—a cough has come on, rapid emaciation, decay, and death.

Post mortem appearances.—Both in horses and dogs, pallor of the organs and tissues of the body generally; in dogs, enlargement of the liver and caseous tumours in the lungs—the latter being probably accidental complications.

(b.) Azoturia.

Under the term of azoturia, or nitrogenous urine, I intend to describe a disease to which attention was drawn in this country by Haycock, who named it, at the suggestion of Mr. James Moore, V.S., London, "Hysteric." In Gamgee's Domestic Animals, the same malady is described as "enzootic hematuria of horses"—"schwaze harwinds" of the Germans, who state that it occurs in horses, and very rarely in mares. Mr. Haycock, on the contrary, says it occurs in mares only, and for this reason has called it hysteric. I have, however, seen it both in mares and horses, and have satisfied myself that in no instance is there blood in the urine, but that the dark coffee colour is due to the presence of urea and colouring matter.

The symptoms are well described by Haycock, who says—"In all cases of this nature which I have treated the disease commenced very suddenly. They [the subjects thereof] began to exhibit an unusual degree of restlessness, to perspire profusely, which symptoms or states were speedily succeeded by a disposition to lie down; by great sluggishness, loss of motor power in the hind limbs; violent spasm of the large muscles of the loins and hind quarters (the gluteal muscles were excessively cramped), and the shoulders; the pulse in two of them rose from sixty to eighty beats per minute, and the respirations were greatly increased; they made several efforts to rise upon their feet, but from the total loss of all motor power in the hind limbs, they were unable to do so; two out of the three every now and then strained violently, and ejected, per vagina, excessive quantities of coffee-coloured urine, which consisted principally
of blood; the perspiration was excessive also. In two cases the more violent symptoms subsided for a time; they became cool in the skin, and partook of food and water, but were totally unable to rise. This improvement did not prove of any long duration; they commenced struggling again with renewed violence with the fore limbs, and continued to do so until they died." Gamgee gives the symptoms of the disease as it occurs in Germany as follows:—"Stiff gait, weakness of the hind quarters, frequent pulse, redness of the visible mucous membranes, anxious expression of countenance, and sweating; a remarkable swelling of great firmness occurs over the loins and hips, and there is a copious discharge of urine of a very dark red or brown colour. Great difficulty of breathing ensues, tetanic symptoms supervene, and death."

The two descriptions agree in most particulars; both contain the diagnostic symptoms of the malady, namely, the tonic spasm of the gluteal, lumbar, and some scapular muscles, and the profuse discharge of dark-coloured urine.

Mr. Haycock was of opinion that the disease had some connection with the period of oestrus, that it was the result of undue excitability, and he compares it with hysteria as described by Copland in his Medical Dictionary. Mr. Gamgee offers no hypothesis as to the nature of the malady. Professor Dick describes it as sprain of the psoe muscles.

At first I was inclined to think, with Haycock, that it was a disease of the mare, but further experience led me to conclude differently, for I have as frequently seen it in the gelding as in the mare; and examinations of the urine, both chemical and microscopic, have convinced me that there is no blood passed by the kidneys, but immense quantities of urea and a less notable quantity of hippuric acid.

The pathology of the disease is, in my opinion, a hypernitrogenous condition of the blood and system generally, due to over-feeding and want of exercise; the excessive secretion of urine and excretion of urea being physiological results due to the presence of effete products—metamorphoses of nitrogenous food—in the blood. The history of every case that I have met with, and of all those recorded by Haycock, points to this. He says—"The first case which I treated, the animal had rested about a week, at the end of which time it was put
into harness upon a very hot day, and driven slowly for a distance of five miles, and was seized on the road. The second case also occurred after the mare had rested a week or a little more, when it was taken out of the stable on a very sultry afternoon, and galloped severely, and shortly afterwards was seized. The subject of the third case rested from Saturday morning to Monday morning, at which time it was put to its usual labour, and driven slowly for about a mile, and was seized ere it had got to the end of the journey, short as it was." The above corroborates my experience of every case of this malady in a most remarkable manner. Varying periods of rest were succeeded by an attack on the first journey, the animals always leaving their stables in higher spirits than usual, and giving rise to the remark, "He never looked better than when he first turned out; in fact we could scarcely hold him, he was so spirited." I never met with a case that was attacked in the stable prior to some amount of exercise. It seems necessary that some degree of muscular exertion be performed, and the only way in which I can account for this is, that the blood before exercise contains a superabundant quantity of albumen unappropriated by the tissues, and that the exercise, by increasing the rapidity of the circulation and of the respiratory movements, induces a rapid oxidation of such superabundant albumen, whereby it is transformed into urea, hippuric acid, &c., with which the blood becomes over-loaded, and the kidneys stimulated to excrete what is proving deleterious. Albumen is occasionally present in the urine, but this is by no means constant; its presence, however, points to an aggravated form of the disease, and is often prognostic of a fatal termination.

The presence of such effete material in the circulation provokes tonic spasms of the muscles, loss of motor power in the posterior, and sometimes, but rarely, in the anterior extremities, tetanic convulsions, and, finally, death, by extreme muscular prostration, simulating motor paralysis. In every fatal case that I have observed, the spasms and convulsions have been succeeded by extreme muscular debility, the muscles contracting but feebly on the application of a stimulus, the heart and diaphragm partaking of this prostration, and the animal dying from asthenia and apnoea. In other cases the animal has overcome the primary and violent symptoms, but has remained partly paralyzed in one hind extremity.
Post mortem examination reveals the blood dark-coloured, having an ammoniacal smell, and semi-fluid; congestion of the lungs; clots of dark blood on both sides of the heart; the bladder filled with dark or coffee-coloured urine, and sometimes softening of the liver and kidneys.

Congestion of the sheaths of the great gluteal nerves has been present in some cases, in which the spinal cord at the lumbar region has been found red, congested, and softened, but in others these appearances have been absent, the spasm and loss of power being due to the effect of the altered blood on the muscular tissue.

Examination of the urine.—The urine is to be examined as soon as possible after it has been obtained from the animal, as it quickly becomes ammoniacal. In every case its specific gravity is much increased—1:185 or higher. It is highest during the first few hours after attack, as it often becomes lighter in colour, even in those cases which succumb after the first day or two. Boiled, the urine generally gives no reaction, except that ammoniacal gas is emitted. Tested with nitric acid, it becomes almost solid, but the solidity is rarely due to coagulation of albumen, but to the precipitation of crystals of nitrate of urea in great abundance. These crystals appear as mica-like scales of a brown colour, and fall to the bottom of the glass. At first the addition of the acid causes much effervescence, the urine being strongly alkaline, containing ammonia carbonate. When the effervescence has ceased the urea is rapidly precipitated, and the liquid loses much of its dark colour. Microscopically examined with a quarter-inch objective, it presents the appearances seen in fig. 16.

![Fig. 16. — Crystals of Nitrate of Urea.](image)

If the serum of the blood is carefully prepared, the crystals of nitrate of urea can be detected in it by the following process:
Take a given quantity of serum, and precipitate the albumen by boiling, filter and evaporate the liquid to dryness over a water bath. Treat the residue with alcohol, which dissolves urea readily, evaporate the alcoholic extract to dryness, and add a little water, so as to make a syrupy mass, which should be plunged into a freezing mixture, and a few drops of pure nitric acid added to it, when crystals of nitrate of urea will soon be found in it.

There is no doubt that this malady attacks mares more particularly during the period of oestrus. This can be accounted for in two ways, independently of any association with hysteria, namely—(1.) Because mares whilst in this state are very often kept off work for a few days; and (2.) They are in a highly excitable nervous condition, and more apt to suffer from spasmodic diseases, the causes of which may be very trivial.

In the spring of 1870 I was called to see a horse in a dying state from this disease. I found that four had already died from it. They were farm horses, which in consequence of the frost had not been worked or exercised for some time. As long as they were kept in the stable they seemed all right, and immediately on the frost giving way they were put to work. They were all attacked, and succumbed in a few days; some of them dying early in the disease, others living for some days; and, what was very remarkable in those which struggled longest, the muscles lost all power of contractility, and in the one I saw there was no rigor mortis after death.

_Treatment._—The therapeutics of this disease may be summed up in a few words, namely,—keep the various excretory organs acting freely, in order to assist nature in expelling the degraded products from the circulation. For this purpose a cathartic or oleaginous aperient ought to be administered without delay. The kidneys generally act freely enough, and need no stimulus; but should they cease to perform their functions, diuretics, and more particularly colchicum, are to be used. The animal should always be placed in a large, well-bedded, dry, loose box, with plenty of short straw or chaff around it, which is to be removed as soon as it becomes damp or wet. If unable to rise, it is to be turned from side to side two or three times a day, or more frequently if it becomes uneasy. Enemas are to be administered until purgation commences, and plenty of diluents allowed. Generally the
horse is thirsty, and will drink cold water freely and to manifest advantage.

There is no necessity to aggravate the disease by either stimulants or sedatives. They always do harm during the first stages of the malady. If, however, towards the third day the animal seems depressed, moderate doses of spirits of nitrous ether may be given two or three times daily; and about this time attempts should be made to get the horse on its legs. If unable to do so without assistance, the slings should be placed under it, and it is to be gradually placed on its feet. At first it will be much disinclined to stand, and will be apt to fall from muscular weakness; but if the limbs are supported and smartly hand rubbed for some minutes, they will regain much of their lost power, the horse will begin to "feel himself," as is commonly said, and will often commence to feed and do well. It should be kept in the slings for a few days, but taken out occasionally for a little exercise; and when allowed to lie down for the first time, it should be carefully watched, as it is apt to knock about very much if unable to rise with ease.

During the first few days the diet is to be of the lightest description and restricted in quantity, but when convalescence has commenced, it must be moderately nutritive and easy of digestion, as much muscular debility exists in the digestive apparatus as well as in the voluntary muscles. At this stage a few doses of nux vomica may be given with advantage.

I have never seen any benefit accrue from external applications to the loins or back. On the contrary, fomentations, frictions, stimulants, or blisters increase the irritability of the animal, cause it to struggle when it otherwise would remain quiet, and do much harm.

If the pathology of the disease be borne in mind, the practitioner will at once see that the symptoms will cease as the morbid material in the blood is eliminated, and that the first and great aim of treatment is to effect this, after which the muscular debility must command his attention; and if there are indications of failure of the heart’s action in two or three days after attack, stimulants are to be administered with freedom.

Any of the ordinary stimulants will answer the purpose, but perhaps we should exclude ammonia, as the blood-poisoning products are too similar to that medicament.
(c.) **OXALURIA.**

A condition of the system manifested by dulness, capricious appetite, loss of flesh, debility, stiffness about the loins, a bran-like scurf on the surface of the body—pityriasis—"hide-bound," and the presence of the oxalates of lime in the urine.

This disease is most commonly seen in hunters or other horses whose work is irregular, and which have to undergo long periods of fasting, as during a long and severe day with the hounds, the result of such long fasting being a weakened or debilitated condition of the digestive organs, whereby the products of the primary digestion are imperfectly formed, and unfitted for assimilation and consumption in the processes of nutrition and carbonization.

The disease is also induced by food rich in saccharine matters, as carrots, turnips, or other roots, more especially if the digestion is deranged. Oxalates may also appear in the urine during recovery from other diseases, more especially during a protracted recovery from an enzootic or inflammatory affection.

Oxalic acid is a product of imperfect combustion or oxidation of the amyloidal and nitrogenous matters of the body. It may also result from an imperfect condition of those matters primarily; a perverted acid condition of the digestive organs, impediment to the respiratory function, or from a superabundance of food, more especially if combined with insufficient exercise. Various vegetables contain oxalic acid—the sorrel—but I am not aware that these are partaken of by the horse, or that they are ever the cause of this disease. The pathological importance of a deposit of the oxalates has been considered doubtful by writers on human medicine. Some writers affirm that they result from chemical changes in the urine whilst in the renal passages, and that their occasional presence is no indication of disease. In our patients, however, their continual presence generally attends a form of indigestion in which an acid condition of the alimentary track is a constant accompaniment.

**Semiology.**—Loss of flesh; capricious appetite; a dry, immovable, scurfy condition of the skin; the horse is said to be hide-bound and scurfy; a desire to lick the walls, and frequent urination of a palish amber-coloured urine, the act of micturition being often accompanied and followed by signs of uneasi-
ness, such as whisking of the tail, or even attempts to lie down, or kicking at the belly with the hind feet. The mouth has sometimes an acid or sour smell, the tongue is covered with a whitish fur, and there is generally a degree of constipation or irregular action of the bowels. An animal thus affected is stiff in the loins, and is easily fatigued.

Etiology.—The causes are to be found in irregularity of feeding, want of sufficient exercise, irregular exercise and work, such as fatiguing journeys with long intervals of rest; improper food; or it may originate in weakened digestion from an unknown cause.

Condition of the urine.—The urine at each emission is scanty; of a pale amber colour; clear, like pale sherry, and is neutral or acid in its reaction. If examined immediately with the microscope, crystals of the oxalates will most probably be detected. In some instances, however, the crystals cannot be detected with the microscope for a day or two after the urine has been passed, the oxalic acid being present in its free state, and afterwards combining with the lime and forming at least two distinctive forms of crystals:—1st. and most common, Octahedra (a); 2d. Dumb-bell (b) (the dumb-bell is very rare in the horse).

—See fig. 17.

![Fig. 17.—Crystals of Oxalate of Lime.](image)

(a.) Octahedral form. (b.) Dumb-bell form.

These crystals are soluble in nitric acid without effervescence, are insoluble in water, and are unaltered by boiling in acetic acid or liquor potasse.
Beneke, a German pathologist, has studied the question of the origin of oxalic acid in the human frame, and has arrived at the following conclusions:—

"1. Oxaluria, a condition which accompanies the lighter or severer forms of illness, has its proximate cause in an impeded metamorphosis—that is, an insufficient activity of that stage of oxidation which changes oxalic acid into carbonic acid.

"2. Oxalic acid has, if not its sole, its chief source in the nitrogenous constituents of the blood and food: everything, therefore, which retards the metamorphosis of these constituents occasions oxaluria.

"3. Such a retardation of the metamorphosis of the azotized constituents of the blood may be determined by the following causes:—

"(a.) Abuse of azotized articles of food (direct retardation).

"(b.) Abuse of saccharine and starchy articles of food (indirect retardation).

"(c.) Insufficiency of the red corpuscles, and (eventually) diminished oxidation.

"(d.) Insufficient enjoyment of pure, fresh, ventilated air.

"(e.) Organic lesion, which may in any way impede respiration and the circulation of the blood.

"(f.) Conditions of the nervous system which bear a character of depression, whether these arise primarily from mental derangement or from pathological states of the blood.

"4. Excess of alkaline bases in the blood, which, as numerous observations tend to show, plays an important part among the etiological conditions of oxaluria; and it is not improbable that an increased production of lactic and butyric acids in the digestive canal, consequent thereupon, impedes the development of the red corpuscles, and thereby generates that chlorotic state which so often occasions and accompanies oxaluria.

"5. Catarrhal conditions of the intestinal mucous membrane, in case they are accompanied by oxaluria, have at most only a common source. They may determine oxaluria by causing deranged digestion, but cannot be considered as its proximate cause."

Oxalic acid differs from carbonic acid in possessing an atom less of oxygen and one less of carbon, and we cannot be sur-
prised at its occurrence in the urine, when we remember how slight a deviation in the oxidation of tissue may cause its formation.

Treatment.—In the first instance, it is necessary to alter the deranged condition of the digestive apparatus, and for this purpose a purgative is often rendered imperative. When the bowels have been operated upon, the condition of the system (the oxalic acid diathesis) is to be overcome, and the digestion improved by mineral acid tonics, the nitro-muriatic acid in preference to others, given in a decoction of gentian or other vegetable stomachic bitter. The diet must be carefully regulated, and all roots and food containing much sugar withdrawn. The quality of the drinking water must also be looked to, and if it contains an excess of lime, it must at once be changed, for if the oxalic acid is to be eliminated from the system it must be removed in a soluble form, and every remedy will fail if an excess of lime is present in the circulation. For the same reason alkalies generally are not to be administered, as they are transformed into oxalates, more or less insoluble, in the body.

Bearing in mind that non-oxidation is a source of oxalic acid, the practitioner will order regular exercise, pure air, and good grooming.

The irritation manifested in the passage of the urine is due to the direct irritation of the oxalic acid and oxalates on the mucous membrane of the urinary passages, and the frequency of the act of micturition is due to the same source. If not very harassing to the animal, no special treatment is required for its removal, for as the urine regains its natural character the irritation passes away. Should it be really a source of much annoyance, enemas containing belladonna or opium may be used.

In some cases of oxaluria, when the mineral acids have failed, the disease has rapidly disappeared when acid phosphate of soda has been substituted.

(\textit{d.}) Red Water, Hæmo-albuminuria (Simonds); Black Water, Bloody Urine, Hæmaturia (Ganges); Muir-Ill, etc.

A disease of the bovine tribe, characterised by the emission of red-chocolate or black urine, containing albumen and the
colouring matter of the blood in a broken down or disintegrated condition. The disease is associated with great prostration, febrile excitement, palpitation of the heart, a double, microtonous, or trembling pulse, pallor of the mucous membranes, and diarrhoea, succeeded by obstinate constipation of the bowels.

The disease is divided into two kinds, namely, parturient and non-parturient red water. The pathology of both is the same, and a description of one will serve for both, except indeed that the parturient form occurs in from eight to fourteen days after parturition.

**Etiology.**—The immediate cause of the disease is to be found in the nature of the food. In the puerperal form the cause is generally traced to the turnips the cows are fed upon. Mr. Cuming of Ellon says that "turnips contain about 10 per cent. of saccharine matter, and 1 or 1½ per cent. of vegetable albumen. A liberal allowance of turnips increases the quantity of milk, the sugar of that milk being directly supplied by the turnips; but the cow cannot make milk out of sugar alone, and the other elements of secretion, namely, the albuminoid casein, not being duly afforded, the tendency is to draw upon the blood, and through that fluid upon the body at large, for what is deficient." This theory can only hold good in reference to the puerperal form of the disease. Red water, however, prevails among calves, stirsks, oxen, and bulls, and extensive experience has shown that impoverished pastures, healthy moors, and woody districts are subject to have the cattle grazing upon them affected with the disease in an enzootic form, during some seasons.

On the Continent the disease has been recognised as connected with damp lands and wet seasons. It occurs in bad weather, and when food is scanty and of inferior quality. It is seen always on pasture lands, and never in stall-fed animals, except in Britain, where it occurs amongst cows fed on turnips grown on damp land.

All authorities are agreed that the disease is induced by food containing an excess of water and diminished proportions of flesh and fat forming matters. I think Mr. Cuming is wrong when he states that a disproportion of sugar produces it. Turnips only produce it when they are given over-abundantly, and
without a due admixture of other food. I am not aware that locust beans were ever known to cause it, and the quantity of saccharine matter in them is very great indeed. Again, it is very satisfactorily proved that when turnips are grown on well-drained and properly manured land, they do not cause the disease, provided the season in which they are grown has not been unusually wet, and if they are used in moderation; but when given indiscriminately, and without due admixture with other food, such turnips are almost sure to induce the malady. Indeed, it may very properly be concluded that red water is due to insufficient feeding. The food may be sufficiently abundant in quantity, but it is defective in quality, the result of such deficiency being the breaking up of the blood and tissues, whereby they are excreted or expelled from the body as so much effete material.

Pathology.—Examinations of the urine in this disease have led to no very definite results. Professor Simonds named the disease hemo-albuminuria, from the fact that the urine always contained albumen.

In the Veterinarian for June 1849 an analysis is reported by Mr. Hughes, a student. The analysis was made in the previous January, and is as follows:

Mr. Cuming of Ellon throws some doubt upon the accuracy of
the above analysis, and gives analyses of his own and of Mr.
Deuchars, V.S., his assistant, which differ from it to some extent.
Being dissatisfied with any reported analysis, I procured some
specimens of urine, and found that it may be satisfactorily con-
cluded that albumen is always abundantly present, and that the
haematin of the blood, escaped from the corpuscles to a great
extent, gives colour to the urine, which may be of a dullish red
or a brownish-black appearance, the difference in the colour
being due to the varying quantity of haematin, and to a chemical
alteration of its iron, arising from the presence of sulphide of
hydrogen and ammonia. The following analysis, made by Dr.
Macadam, will show the chemical constitution of a sample of
urine, selected as on average one from several which were sent
to me from various parts of England, Scotland, and Ireland:—

26th March 1874.

Analysis of Samples of "Red Water" received from Principal
Williams, of the New Veterinary College, Edinburgh.

Specific gravity at 60° F. 1941 (Water = 1000).

It may be mentioned that every specimen emitted a more or
less powerful odour of rotten turnips, and was strongly alkaline
in its reaction. Microscopically examined, crystals, as shown in
the figure, of cholesterine, hippurates, phosphates, and epithelial scales were found more or less abundantly.

Fig. 18.

(a) Cholesterine.  (b) Phosphates.  (c) Mucous corpuscles.

From examinations of samples of urine, and from the history of cases kindly furnished by numerous veterinarians, as well as from what has more immediately come under my notice, I am induced to conclude that the disease originates in an impoverished condition of the blood, arising from want of proper food; that the albumen of the blood is thus degraded in quality, and as such is unfit to be appropriated for the nourishment of the tissues, and is consequently excreted by the kidneys and expelled from the body; that the blood globules are in a broken-down or disintegrated condition, arising from solution of their outer layers or cell walls, when their coloured interior—haematin—escapes, which, mixing with the serum of the blood, and being eliminated by the kidneys, gives the characteristic tinges to the urinary secretion. This mal-condition of the blood is succeeded by diseases of various organs; most notably congestion of the liver; irritation of the intestinal mucous membrane, as expressed by diarrhoea; paralysis of the intestinal canal, giving origin to an apparent constipation, and in some instances to severe cerebral disturbance, manifested by delirium and convulsions. The irregularity of the heart’s action, as well as the feebleness and peculiar trembling or thrilling of the pulse,
are also expressive of a mal-condition of the blood, and characteristic of the anaemic state.

The post mortem appearances indicate a condition of anaemia. The subcutaneous tissues are white; the blood-vessels and cavities of the heart are empty, leading one to suppose that the animal had been bled to death; ecchymoses are seen on the serous membranes, and on the lower surfaces of the kidneys; the uterus in the parturient form contains some dirty coloured mucus, and sometimes presents spots of so-called inflammation. In no case are there indications of nephritis, the kidneys, on the contrary, being blanched, and the uriniferous tubes enlarged, evidently dilated with a viscid fluid. The rectum generally contains faeces covered with a dark-coloured mucus; in nearly all cases the liver is darker than is natural; the gall bladder distended sometimes with a dark viscid, sometimes a thin yellow bile. The contents of the lacteals and thoracic duct are occasionally found to be of a dark red or brown colour; but the most constant pathological conditions, in addition to the anaemia, are softening and engorgement of the liver, and fulness of the gall bladder.

Semiology.—In the parturient form, the disease is developed in from eight to fourteen days after parturition, with general derangement, diarrhoea, and loss of milk. In all cases, when examined particularly, the pulse indicates considerable constitutional disturbance, being 80, 90, 100, or upwards, having a peculiarly full beat, thrilling or double; the artery relaxed, and easily yields to the onward wave of blood; the back is arched, and in some cases there is considerable straining. Constipation succeeds the diarrhoea, and the faeces passed are dark in colour. Palpitation of the heart is apt to occur, whilst the pulse becomes feeble and feeble. Mr. Steel of Biggar says that the vagina has, in the parturient form, a contracted or puckered-up appearance; that the milk drawn from the cow prior to the attack is particularly disposed to froth in the pail, and sometimes has a red sediment at the bottom after standing.

Treatment.—The preventive treatment.—Seeing that the disease is one arising from insufficient nourishment—"a disease of the poor man's cow," as expressed by one writer—is a simple matter. About the parturient period, great care is to be taken that the animal's food be of a proper quality, in proper propor-
tions as to all its flesh-forming, heat-giving, and saline constituents. If the malady be manifested in other than parturient animals, its source of origin will generally be found to exist in the pastures, which are on undrained, impoverished, or naturally inferior soils, in rank, unnutritious food, and in defective feeding of all kinds. If the causes be removed—the animals properly fed—it will be found that the further manifestation of the disease will be arrested.

The medicinal and hygienic treatment of the disease is very varied and often unsatisfactory. Its pathology, however, points to a rational method, namely, that the great end in view is the restoration of the blood to its physiological condition by the administration of albumen, which can be easily effected by giving eggs and milk; and several of the veterinarians who sent me samples of urine, have, on my recommendation, pursued this line of treatment with very successful results. In addition to the highly albuminous food, stimulants, and the chlorate of potash, from its well-known action on the blood, may be given with benefit. As to the administration of purgatives, I am of opinion that the more drastic ones should be avoided, and that the diarrhoea, which is a very constant symptom at the commencement of the disease, should be encouraged by mild oleaginous aperients, as it is the means by which the unsuitable food contained in the alimentary canal is expelled from the body. If there be any appetite, it is clear that food of a nutritious but easily digestible nature must be allowed in moderation.

Treatment by styptics.—Some veterinarians, looking upon the malady as hematuria, administer styptics and astringents, for the purpose of restraining the bloody discharge. This view of its pathology is incorrect, and consequently the treatment which is based upon it need not be discussed.

(v.) Asthma—Broken Wind.

Asthma, like diabetes, might with propriety be classified amongst constitutional diseases, for now and then it arises from no cognizable cause. I have, however, deemed it advisable to classify it with the dietetic diseases, as in the great majority of instances it originates from errors in feeding.

Definition.—A non-inflammatory disease, characterised by
difficult and peculiar breathing; the inspiratory movement is performed with ease, the expiratory by two apparent efforts. The difficulty in breathing is constant, but is liable to remissions and severe exacerbations. A peculiar cough, called “the broken-winded cough,” is a constant symptom; indigestion and flatulence aggravate the dyspnoea.

_Etiology._—The causes of broken wind, as laid down by writers, are very numerous and complicated. Youatt says that emphysema of the lungs is present in almost every case that he has examined. Haycock ascribed the disease to hepatization and induration of a portion of one or both lungs, chronic disease of the digestive organs, or of the nerves of the respiratory apparatus, rupture of the diaphragm, and inflammation of a low subacute character of the mucous membrane of the bronchial tubes and minute air cells. Gibson attributed it to enlargement of the contents of the chest. Dr. Lower supposed that it arose from rupture of the diaphragmatic nerve. The Professors of the Veterinary College at Lyons (1826), after performing a variety of experiments, were led to conclude that the dyspnoea arose from a reversed situation of the diaphragm, caused by nervous derangement. M. Godine, Jun., professor at Alfort, considered it as a natural defect in the normal and relative proportions of the right and left side of the heart. M. Demussy, in a Memoir to the Royal Society of Agriculture of Paris (1823), affirms that by direct observation he discovered that those districts of France where hay or other dry food is most used, are subject in a peculiar degree to broken wind among their horses.

Coleman said it originated in mechanical rupture of the air cells. Blaine supposed it arose from emphysema of the lungs, due to the formation of gases within the lung tissue.

To give my own opinion, I have no hesitation in asserting that broken wind is generally due to improper food, more particularly to bad, musty, or coarse hay, containing a large quantity of woody fibre, from being allowed to become too ripe before being cut, and to a superabundant allowance of hay of any kind, with a deficient supply of corn.

Mr. Anderson, V.S., Glasgow, has very carefully investigated the causes of broken wind, and has been led to conclude that in most instances it is due to habitual over-loading of the stomach with coarse, indigestible food; in some cases the stomach has
been found much enlarged, and containing masses of dry food adherent to its walls.

In some districts the disease prevails, or used to prevail, to a great extent. In some parts of Wales I have very frequently noticed many broken-winded horses; and upon inquiry, have discovered that their fodder has been of the worst possible description. I quite agree with Professor Gamgee that broken wind is at first a purely nervous affection, dependent on the condition of the digestive system, and in which the pneumogastric nerve is especially involved, and that the organic lesions are the effects of the nervous disorder. Some horses are peculiarly prone to suffer from broken wind, where no fault can be detected in the method of feeding. Such animals are constitutionally predisposed to indigestion, tympany, and irregularity of the bowels; they are generally round, shallow-chested horses, but are not bad thrivers before they become affected in the wind.

Pathology.—The smaller air tubes are surrounded by involuntary muscular tissues; in broken wind, owing to the irritation of the par vagum, the function of this muscle is interfered with. In the early stages, and during the paroxysms of broken wind, it is spasmodically contracted; in the later stages most probably it is paralyzed; in either condition there is arrest of respiration. The irritation arises from the action of indigestible food upon the cardiac branches of the vagus, and is reflected to the pulmonary branches of the same nerve. Recent experiments by Bert have convinced him that the lungs contract under the influence of the vagus, branches of which, it will be remembered, supply both the lungs and stomach, as well as other organs. The action of the bronchial muscle surrounding the tubes is brought into play during the expiratory movement, whereby the lungs are assisted in expelling the tidal air. The same thing happens in the lungs of a horse suffering from broken wind as in the lungs of a human being suffering from asthma. Owing to nervous irritation, there is arrest of respiration, and this can occur either in expiration or in inspiration; the arrest during expiration being the more easily induced, indeed "in some animals it is impossible to obtain arrest during inspiration."—(PAUL BERT.) The arrest takes place in the act (inspiratory or expiratory) which happens to be going on at
the instant of application of an irritant to the nerve; "the lung being, as I take it, seized and fixed by spasm, and immobility of the bronchial muscles."—(Dr. J. C. Thorowgood.)

In the horse the arrest is always during the expiratory act, which, in consequence, becomes prolonged, difficult, and calls for a double contraction of the abdominal muscles to force the air out of the distended and now immobile bronchial tubes. I have noticed that very round-chested horses sometimes become broken-winded without apparent cause, and I conclude that difficult expiration may occur in them from limited thoracic contraction. When the conformation of the chest is round, respiratory movements, at least thoracic movements, are very limited in extent; for when the chest is naturally round, its conformation is but little altered during the respiratory movements. An animal so formed is incapable of taking a deep inspiration, and as incapable of performing a strong expiration; the lungs of such contain much residual air, the thoracic walls are more resonant on percussion, and in them probably arrest of expiration is most easily induced. Every horseman knows that round-chested horses, although apt to put on fat and look well, are not so capable of performing the same severe and fast work as deep-chested animals; in fact that they are "not so good in their wind."

The abnormal condition of the bronchial tubes and air vesicles is at first due to purely nervous derangement, but this is very rapidly succeeded by organic or structural change. Inflation of the air cells to excess prevents the free circulation of the capillary blood-vessels, and thus the nutrition of the bronchial muscle and mucous membrane is weakened; degeneration succeeds, and the lungs become more and more emphysematous; the air cells undergo dilatation, their parietes become stretched and disorganized, and air now infiltrates into the meshes of the connective tissue of the lungs. In this manner both vesicular and interlobular emphysema may be induced. Various other changes may occur in the thoracic organs, the most constant being hypertrophy and dilatation of the right side of the heart. By bearing these facts in view, much of what seems irreconcilable may be understood, and what have been looked upon as causes will be seen to be but mere effects.

The morbid anatomy of broken wind differs according to its duration at the time of the animal's death, which is generally due
to another disease or to an accident. If death occurs soon after asthma has been manifested, no morbid change may be detected. Professor Dick said he had examined many cases where no disease could be discovered. In other cases the stomach has been impacted with food. This impaction of the stomach will only be observable in an animal which has died suddenly, or has been killed, as in one suffering from another disease the appetite would be impaired, and the horse would not eat for a time prior to its death.

If the disease has continued for a period of time, the following lesions may be detected:—Emphysema of the lungs, chronic thickening of the bronchial tubes, dilatation of the air vesicles, with anemia, degeneration, and rupture of their walls, pallor of the pulmonary parenchyma, and eccentric hypertrophy of the right side of the heart, or the whole cardiac substance may be variously altered in structure.

**Symptoms.**—The inspiratory movement is performed with ease, but the expiratory by two apparent efforts, at the conclusion of which the muscles relax, and the flanks fall with peculiar force. There is a singular cough, which seems to be “ejaculated with a sort of grunt through the upper part of the trachea, perhaps from a sympathetic connection with the parts below.”—(BLAINEK.) Auscultation will detect the respiratory murmur weakened or absent; there is a loud, sonorous, sibilant wheeze, heard particularly loud towards the posterior part of the chest. Rhonchus and sibilus of every tone and variety may be heard all over the chest. There is stagnation of air in the lungs, and the sounds may change both in character and site, owing to the varying clonic contractions and relaxations of the bronchial muscle. A rubbing sound is heard, if rupture of air cells has occurred, denoting the presence of air in the lung tissue. On percussion, the resonance of the thoracic walls is increased, showing that the lungs are distended with air; the chest itself seems rounder than is natural, and the thoracic movements are very limited, whilst the abdominal ones are violently increased during a paroxysm. The symptoms are much more severe after the animal has been fed, and after the spasmodic fit has passed away, the breathing may be tolerably easy until it is fed again. The digestive organs are weak and easily disordered; flatulence is a prominent symptom; and the animal is often harsh and dry in its coat, pot-bellied, and unthrifty.
Treatment.—Great attention to diet. The food and water should be carefully regulated as to quantity, and be of the best quality. Feeding on bran mash, containing a few ounces of linseed oil with lime water, has proved serviceable in the practice of Mr. Anderson of Glasgow. A purgative should occasionally be administered, and the alimentary track always kept in proper order.

The old farriers used to make a supplementary anus for the horse by passing a red-hot iron into the rectum from immediately below the tail, through which a leaden ring was inserted, to keep it patent. There is no need to resort to this barbarous and insane method; but they supplied a reason for doing it, namely, that the artificial anus allowed the flatus to escape from the bowel easily, and that it did away with the disagreeable sound which accompanies that act when it is naturally performed.

The symptoms of broken wind may be palliated by all methods which improve the digestion, and by remedies that are calculated to give them tone; hence arsenic, alkalies, bitters, more especially nux vomica, and the various tonics are serviceable. All mere remedies, however, must be of secondary importance to hygiene and dietetics.

"Horse-coupers" resort to various methods for relieving the breathing of broken-winded horses. These persons know well enough that the animal breathes moderately well when the stomach is empty; they therefore take good care to keep it short both of food and water, and give it a sharp trot to unload the bowels. Shot, lard, gunpowder, opium, and other remedies are then poured down its unoffending throat, and most of these remedies seem to exercise a sedative or "stilling" effect, and the unwary purchaser only knows too late how cleverly he himself has been "sold."

There is one consolation, if not for the buyer, at least for the public generally, and that is, broken wind, like many other diseases the results of ignorance, is fast becoming a thing of the past.

LEAD POISONING—LEAD PALSY—PLUMBISM.

Definition.—A series of morbid phenomena induced by the absorption of the salts of lead contained in solution in the drinking water or in the food.
Lead poisoning is a disease generally confined to those districts of the country where lead smelting is carried on. It may, however, occur accidentally in any part where animals have access to lead paint, or splinters of leaden bullets, which are often scattered about in quantities near rifle targets. It also occurs in cattle pastured in fields manured with town ashes, which often contain scrapings of paint-pots, waste paint, &c.

In whatever form the lead gains access to the stomach, it must be rendered soluble before it is absorbed into the circulation. Lead paint, leaden bullets, and other insoluble forms of lead, are acted upon by the acid secretion of the true digestive stomach, and are thus rendered soluble and fit for absorption into the animal economy. The portions of insoluble lead found in the rumen, &c. of horned cattle are to be looked upon as indicating that lead is present, and that some of it is absorbed into the system, rather than as actual causes of any symptoms present prior to death. Lead in its metallic state appears to be devoid of medicinal or poisonous action. Four ounces of shot were given to a dog at the Veterinary School of Lyons without effect. The metal may sometimes, however, be converted within the body into an oxide or active salt.—(Finlay Dun.) Shot is used by low horse-dealers to relieve the symptoms of broken wind, and doubtless some of the lead is dissolved by the gastric acids, and acts as a sedative upon the gastric nerves.

Plumbism, or lead poisoning, results from the absorption of lead into the circulation. It is thus diffused through the whole body, and exerts its toxic action upon all the organs and tissues of the animal frame, but it does not affect all parts alike, but accumulates in some more than in others.

Dr. George Wilson (see Monthly Journal of Medical Science, May 1852), found that the spleen yielded lead most abundantly; next to the spleen the liver yielded most; then the lungs, afterwards the kidneys, then the heart, and the intestines least. Lead has also been found in the brain and in the muscles; and the blue line observed in the gums of animals and men poisoned with lead, is supposed by Toures to be due to the lead in combination with the tartar of the teeth.

Lead having once entered the body, leaves it very slowly, and may be detected in it months after an animal has ceased to receive lead with its food or water. It enters into combination
with the tissues of the body, and is retained in the system as an insoluble compound, and only leaves the body on the breaking up or disintegration, medicinally or otherwise, of such insoluble compound.

The symptoms of slow lead poisoning in the lower animals are, capriciousness of the appetite, loss of flesh, convulsive fits, a blue line seen on the gums where teeth are present, the gums in the interdental spaces showing no trace of this colour. Colic is sometimes absent, and constipation is not so constant a symptom as in man; indeed I have repeatedly seen a diarrheic condition of the bowels with leaden-coloured and fetid stools. In the horse, roaring is considered, in Wales, the first symptom of lead poisoning, and every roarer in the lead districts about Holywell and Flint is said to have had lead (plumb). Mr. Shenton of Bakewell, in a letter to Mr. Finlay Dunn, thus describes the symptoms of lead poisoning in eleven horses which came under his observation in 1852:—"There was a rough, staring coat, a tucked-up appearance of the abdomen, and a slightly accelerated pulse; in fact, symptoms of febrile excitement, which usually passed away in about a week. About this time large quantities of grey-coloured matter were discharged from the nostrils, and saliva from the mouth; but at no time was there enlargement of the submaxillary, lymphatic, or salivary glands. Neither was there constipation of the bowels, which appears to be nearly always present in cases of lead poisoning in man. Fits and partial paralysis came on at intervals; and when the animals got down they often struggled for a long time ineffectually to get up again. The breathing up till this period was pretty tranquil, but now became so difficult and laboured that the patient appeared in danger of suffocation. The pulse was in no case above sixty or seventy; and I ascribed the difficulty of respiration to a paralysed state of the respiratory apparatus. The animals did not live more than two or three days after these symptoms appeared.

"The post mortem appearances varied but little. The lungs and trachea were inflamed; the lungs engorged with large quantities of black blood; the trachea and bronchi filled with frothy spuma. In all cases but two the villous part of the stomach presented isolated patches of increased vascular action; and in all cases the intestines, especially the large ones, were inflamed.
The blind pouch of the caecum was nearly gangrenous. There was nothing remarkable about the liver, spleen, or kidneys, except that they were of a singularly blue appearance. The brain and spinal cord were not examined."—(finlay dun’s materia medica.)

Lead palsy in man is characterised in its later stages by the blue line around the teeth, ulceration of the mouth, colic, and epileptic fits, preceded, however, by palsy of the upper extremities. The extensor muscles of the hands and fingers become first paralyzed, so that when the arms are stretched out the hands hang down by their own weight, causing what is termed "wrist-drop." This paralysis is succeeded by atrophy of the affected muscles.

In the diagnosis of lead palsy in man the electric current plays an important part, for it is found that when the palsy is induced by lead the excitability of the muscles is much diminished, whilst it is normal in ordinary paralysis. "Therefore, when the muscles of a paralytic limb move well under the influence of the electric current, we may fairly conclude that there is no lead in the system."—(dr. althans on paralysis, neuralgia, &c.)

Mr. herapath reports in the Chemist for 1855 (see f. dun’s materia medica) some interesting cases of lead poisoning, which followed the erection of smelting furnaces on the mendip hills in 1853. The inquiry appeared to commence half a mile from the chimney, and to extend half a mile further. Oxide, carbonate, and sulphate of lead were found on the herbage, hedges, and hay. On the live stock "the effects of the metal were, a stunted growth, a leanness, shortness of breathing, paralysis of the extremities, particularly the hinder ones, the flexor muscles of the fore legs were affected, so that they stood upon their toes, swelling of the knees, but no constipation or colic as in the human species; in a few months death followed. In the young the symptoms were more conspicuous and the mortality greater. Lambs were yeamed paralytic. When three weeks old they could not stand, although they made great efforts to do so. In attempting to feed them from a bottle they were nearly suffocated from paralysis of the glottis. Twenty-one died early out of twenty-three. Colts also died; and those that lived could not be trotted 150 yards without distressed breathing. Pigs confined to the sty were not injured, but if allowed to roam were soon affected. The milk of cows and sheep was reduced in quality and quantity,
and cheese made from the former had less fat in it. I found in the milk of both minute traces of lead. The dead subjects showed the mucous surfaces to be paler than natural. The lungs had large portions of a dark red colour, with circumscribed edges, not like ordinary inflammation, but evidently surcharged with fluid. There was a blue line seen in the gum of the lower jaw, which Dr. Taylor said in court was not caused by lead poison, as it did not occur, as in the human subject, on the upper edge of the gum, but where the gums first come into contact with the teeth, about three-sixteenths of an inch below the top edge. I therefore dissected out this line, which was about three-quarters of an inch in length, and the thickness of sewing cotton; and by aid of carbonate of soda and the blow-pipe reduced a spangle of lead from it, quite visible to the jury without the aid of the microscope.”

I am not aware that there are any cases on record of animals poisoned by water conveyed in leaden pipes; such a thing is not, however, impossible, and where other sources of lead are non-apparent, it will be advisable to search into this.

Treatment.—In the rapidly developed form of lead poisoning from the accidental ingestion of lead paint, bullet spray, &c., the treatment must be directed to prevent the solution of the lead in the stomach and intestinal canal, by administering such agents as enter into combination with lead, forming insoluble combinations. For this purpose the bowels are to be acted upon by a solution of sulphate of magnesia, to which sulphur and sulphuric acid have been added. By this means the lead in the intestines is converted into an insoluble sulphate and sulphide. If pain be present, opium or hyoscyamus is to be added to the purgative. The acid is to be continued for some time, as it is only by keeping the digestive apparatus charged with it that the solution of the lead by the gastric juices can be prevented, for the thin crust of sulphate, which probably forms on the surface of the portions of lead, may be thrown off, and the metal, or its oxide or carbonate, as the case may be, again exposed to the action of the gastric juices.

In addition to the purgative and acid, diluents are to be freely administered, and purgation actively kept up for some days. It is also necessary to keep up a copious discharge of urine, with the view of eliminating the absorbed lead from the body.
When the bowels are thoroughly acted upon, and if the sulphuric acid does not seem to agree with the animal, sulphur and vegetable tonics may be substituted. The sulphur is partially transformed into sulphuredt hydrogen, which combines with the lead, and forms an insoluble sulphide.

In the slower form of lead poisoning, and where the lead has been slowly accumulating in the system, it will be well to consider the chances of success before attempting a cure; and in none but the mildest cases should this be attempted, as the termination will prove neither creditable to the practitioner nor profitable to the owner.

In all cases a small dose of the sulphate of magnesia is to be administered, and when this has operated, the elimination of the poison is to be attempted by the iodide of potassium.

The principle upon which the iodide of potassium acts has been pointed out by Melsens, who assumes that the lead is retained in the body as an insoluble compound with the tissues. The iodide, after its absorption into the blood, combines with the lead, and forms with it a new and soluble salt. The poison is thus liberated from its union with the injured part, dissolved out from the damaged fibre, and once more set afloat in the circulation, and along with the remedy cast out with the urine. Great caution is at first necessary in using this remedy, as at the moment when the compounds, fixed in the body, become dissolved or transformed, the phenomena of acute poisoning may occur. The dose must therefore be small at first, and either increased or diminished, as the patient seems to bear it.

Galvanism is also recommended for lead poisoning in man; and, if necessary, may be tried in the case of a valuable horse or cow.

It will be apparent that removal of animals from the source whence the lead is obtained must be the first step in the treatment.

The soluble salts of lead, such as the acetate, when given in poisonous doses, cause nausea, quick, small, hard pulse, colic, stiffness of the limbs, paralysis of the optic nerves, insensibility, and death; and on post mortem examination the gastric mucous membrane is found grey, and of a macerated appearance, owing to the chemical action of the salt.
PARAFFIN OIL POISONING.

I have met with one instance where several head of cattle on a farm were slowly poisoned by drinking from a stream into which the refuse from paraffin works was discharged.

The symptoms were, gradual loss of flesh, and a persistent diarrhoea, and it was only on a post mortem examination being made that the cause of death was discovered. The appearances were as follows:

Anaemia, wasting of the muscles of the body generally; absence of fat, and other signs of a prolonged mal-nutrition; the characteristic lesions were discovered on opening the abdominal cavity. The intestines had a greyish-black appearance throughout, and were covered with very dark grey or blackish spots of a dull appearance. These spots were found to consist of the various intestinal glands, surcharged with the pigmented matters of crude paraffin. The glands of the mesentery were more or less enlarged, and presented the same dark appearance; the lacteals were of the same colour, and were found to contain paraffin; the liver presented nothing very unusual, but the kidneys, more especially on their inferior surfaces, were covered with the dark spots.

These animals, at least those which I had the opportunity of seeing, had been removed from the field, through which the polluted stream flowed, some months prior; they had continued to eat moderately well, but everything they took seemed to pass through the intestinal canal as if the power of absorption had been entirely lost; and when the condition of the glands and lacteals was examined, this could be accounted for; indeed it may be said that the animals had died from slow starvation, arising from impermeability of the chyle vessels, due to their being blocked up by crude paraffin. Although so long a time had elapsed since the paraffin had obtained access into the body, the characteristic smell was retained; and even many months after they were removed from the body, and preserved in spirits, the odour was still recognisable.

RHODODENDRON POISONING.

Several cases of poisoning by the Rhododendron hybricum having been observed by my late student, Mr. Gun, Veterinary
Surgeon, Beauty, he kindly wrote me the following particulars, which are well worthy of attention:—

"On 8th April last I was asked to attend a lot of fourteen cattle, one and two-year-olds, and on examination the following symptoms were noticeable:—staggering, swaying from side to side, partial paralysis of hind extremities; some of the animals would press their heads to the wall and strike out with their fore limbs, as if endeavouring to get forward, then vomit a green, mpy spuma. One, a yearling stirk, was unable to get up, the hind extremities being completely paralyzed; eyes staring and fixed in their sockets, pupils not dilated, mucous membranes very pale, great straining, passing small quantities of hard, dark fetid feces covered with mucous. The symptoms varied very much, as some of the animals, especially the two-year-olds, would lie down during the spasms of pain, and kick the belly with the hind legs. Vomition was a marked symptom, and came on at intervals, when the animal would groan with pain, vomit, then a spasmodic cough came on, which lasted for a few minutes. When administering medicine, if the animal's head was much raised above the level of the body, the creature would instantly fall as if struck with an axe. On examining the substance vomited, it was full of the flower buds, leaves, and young shoots of the rhododendron in a semi-masticated state. An inspection of the park grazed by the cattle was made, when about three cart-loads of the prunings of rhododendron were found thrown over the fence by the gardener; the prunings having been recently, as was seen, eaten of by the cattle.

"Treatment.—Linseed oil, with potass carbonate, and small doses of tincture opii in the cases suffering from colic was in every instance successful. The yearling stirk affected with paralysis was treated as above, with the addition of the iod. potass., which in a few days had the desired effect.

"P.S.—The first symptoms of illness were noticed fifteen hours after the cattle had eaten part of the prunings."

YEW POISONING.

Considerable difference of opinion seems to exist as to the poisonous or non-poisonous properties of the leaves of the yew tree; some maintaining they are not poisonous except in a
partly dried or decayed state, whilst others state that cattle can
cat them with impunity, either dry or green.

Numerous instances are, however, recorded which prove that
the yew is poisonous to cattle, sheep, pheasants, &c.; and my
own experience enables me to agree with this opinion, namely,
that the yew, English and Irish, is poisonous, both in its
green and its dry state.

Professor Tuson (Veterinarian, January 1877) says, “The
whole subject of poisoning by yew is so important, that I have
undertaken to investigate it, in the hope of being enabled to
determine the nature of the toxic principle of the plant, as well
as to explain away the many contradictory statements that have
from time to time been made relative to its fatal effects.”

It is to be hoped that Professor Tuson will be able to perform
his promise upon a matter so very important. By doing so
he will confer a benefit on agriculturists and the veterinary
profession.

The symptoms are rarely noticed, as the toxic action is very
rapidly fatal, destroying life without there being any very decided
manifestation of symptoms beyond loss of appetite, great pro-
stration, feeble pulse, coldness of the surface of the body, and
rapid sinking of the vital powers.

The post mortem appearances are equally unsatisfactory, and
but little can be detected beyond the presence of the leaves and
twigs in the stomach.

In investigating into the cause of death of one lot of cattle
poisoned, several of which were found dead, it was discovered
that some clippings from yew trees had been thrown into the
park the previous evening, and in those which had died first
the poison was found in the greatest abundance; others of the
cattle lingered for several hours, and in these the leaves were
less in quantity.

From what I observed in making the examination, it would
appear that it is not essential that the yew leaves should pass
beyond the rumen to exert their toxic properties, as in some of
the cases no leaves were found beyond this viscus, whilst in others
a few were found in the reticulum; in those that lived the
longest some of the leaves had reached the omasum. No doubt
some of the juice expressed during mastication would become
absorbed and cause death.
Treatment.—The indications for treatment are the removal of the toxic vegetable as quickly as possible; and, provided the cause has been discovered by the history of the occurrence, or the post mortem examination of the animal or animals already dead, and seeing that vomition is induced with so much difficulty, I see no objection to the performance of rumenotomy, in order to remove all the contents of the rumen; but before resorting to such an operation, the practitioner should endeavour to overcome the effects of the poison by large and repeated doses of stimulants, such as ammonia and alcohol, friction to the skin, and warm clothing. Should this succeed, the operation may not be necessary. At the same time, it must be remembered that, even if the first effects be thus obviated, the animal will continue in danger until the poison has been expelled. The process of ruminating re-established will again subject the plant to the action of the saliva; its remaining toxic properties being thus set free may induce a fatal collapse, while perhaps all has been thought secure. Purgatives will be essential, and ought to be administered without delay.

Milk Sickness.

A form of disease in which the milk and flesh become poisonous, and which, when partaken of by man or animals, induce a violent and even fatal disease.

It appears, as reported by Professor Law of Cornell University, that the disease has been observed by Professor Kerr every summer in the mountains of the Blue Ridge, which runs down to the western portion of North Carolina; among the hills farther south by Dr. Salmon; by Drs. Phillips and Schmidt on the upper water of Scioto, Ohio; and by Mr. Beardsley in Illinois, and adjacent States.

Etiology.—Mr. Law says—“There is no uniform geological condition in the different unhealthy districts to account for their dangerous tendencies. Dr. Phillips says—‘It is found in localities among the Green River hills in Kentucky; it occurs in some localities along the Wabash River in Indiana, as well as here and there in our own heavily timbered uplands in north-western Ohio.’ And yet a constant condition of its prevalence is the unreclaimed state of the land on which it appears. In the Carolinas and Georgia it is found only on the highest
MILK SICKNESS.

mountains; and in Kentucky, Ohio, Indiana, and Illinois, only on the heavily timbered lands or marshy river bottoms in their virgin condition. But the removal of the primeval forest, the drying of marshy spots, and the general cultivation of the soil, is the signal for its disappearance; and thus Dr. Phillips again remarks—'In many localities where it formerly prevailed to a dangerous extent within the memory of the present generation, as in Green and Madison counties, in the State of Ohio, it has now, by reason of the cultivation of the soil, been entirely exterminated. Indeed, the disease may be said to be rapidly disappearing before our extending civilisation.'

"The recent microscopic observations of Dr. Phillips have done more to elucidate the cause of milk sickness than all the wild hypotheses and crude observations of a century before. He has found vegetable organisms in the blood; and as these will explain fully all the peculiarities of the disease, they may be provisionally accepted as the probable disease germs. He says—'In the month of June last, I had under my care a typical case of milk sickness. I made a careful microscopical examination of the urine every day; and upon the fourth day after the case came under my care, I drew a few drachms of blood, and immediately placed it under the microscope at the bedside, while yet warm and liquid. I found it contained a great number of living, moving spiral bacteria, similar in their general appearance to those spiral bacteria described by Professor Lebert as abounding in the blood of relapsing fever patients. I also found in the urine of that patient those same spiral bacteria, and, co-existing with them, the spher-o-bacteria, in segments of two to six or eight. I had opportunity to examine the blood of but one patient; the urine of several was obtained and examined, furnished from patients under the care of one of my professional neighbours—all showing the presence of both these described forms of bacteria. I sent specimens of the blood and urine to a professional friend, having a state reputation as a microscopist and pathologist, and had the pleasure of receiving, within a few days, a full endorsement of my observations." 1

"This will sufficiently account for the fact that particular districts, fields, woods, waters, or plants are at times found to be

1 It ought to be stated that Dr. Schmidt denies the existence of bacteria in the blood of his cases.
infecting; while the same plants or waters, containing identical chemical elements, are at other times or places innocuous. It will further explain why only a certain proportion of the animals or men exposed to the morbid influence succumb to it; while the remainder, whose systems or vital fluids are in a condition chemically incompatible with the propagation of the bacteria, escape. It is quite in keeping with the fact that the disease is produced in widely different conditions of climate, vegetation, soil, geological formation, and management; and that no combination of these is able to produce it, unless the disease germ has been introduced. It explains, too, the permanent preservation of the virus in cheese and other comparatively stable products of the sick. It is equally in keeping with the following circumstances, relating to what may be considered predisposing causes of the disease:—

"The excess of effete matters in the blood evidently favours its development. Thus, overwork, severe exertion—even for a limited time—want of sleep (as in the case of the members of a family watching with a sick relation), a fit of constipation, or a slight attack of malarial fever, all strongly conduce to the development of the malady. It is curious to note that children often suffer less than adults, probably because their emunctories are usually more free, and they are less exposed to exhausting and depressing conditions. In infected cattle, the symptoms are easily developed or aggravated by subjecting them to fatigue; and in milk-sick districts, it is a common practice to test the soundness of stock by giving a good run before purchasing.

"Another very remarkable fact is, that milch cows rarely show the disease, though conveying it to other animals through their milk. Dr. Phillips says—'It is not unusual, where persons suffer from this disease, to find, at the same time, calves using the same cow's milk sick with 'trembles;' while the cows are to all appearance in perfect health. The dry cattle are much more frequently attacked with 'trembles' than cows which are secreting milk in abundance.' To the same purpose Dr. Schmidt remarks—'Cows giving milk do not show the disease at all, but their calves have it all the time as long as they suck the milk; dogs fed on milk get it.' Dr. Phillips says—'A calf gets it from the cow in the milk,—the calf dies; and the pigs which eat the carcase get the disease and die; the dog which eats the pig, and
Milk Sickness.

the buzzard which eats the dog, all in due time contract the same disease. Dr. Schmidt and others speak in similar terms.

"This transmission of the disease through a long series of successive victims, which has been shown in 'scores of careful observations,' demonstrates the important fact of the specific nature of the poison and its multiplication within the system; while any simple mineral or vegetable poison in similar circumstances would soon have been rendered inert by dilution.

"The presumption is that all races of domestic animals are susceptible, and may contract the disease, either from the milk, flesh, or other products of the sick, or directly from ingestion of the poison in food and water. Phillips even suggests the air as a possible medium of infection, but adduces no facts in support of the opinion.

"Symptoms.—In milk cows these may be so slight that they are entirely overlooked, unless the animal is excited. The outlet for the poison through the mammary secretion appears to protect these, in a great measure, from the graver phenomena. When violently excited, however, and especially when driven fast for some miles, they are seized with a rigor and all the more dangerous symptoms of the disease. The breath, too, has at all times that putrid, sweet, mawkish smell which characterises the disease in all animals.

"In steers, and other dry cattle and sheep, the condition is characteristic, even in decubitus: a position which is maintained by the animal as much as possible, evidently because of the great nervous prostration and extreme muscular weakness. The head resting on the ground, the sweetness of the breath, the blood-shot eyes, and the staring coat, are marked features, though appetite and rumination may be preserved. The worst cases lie prone, with head extended on the ground, and show an utter indifference to all sense of fear or danger; and the wildest of them whine under the prostrating influences of the disease, and allow themselves to be handled in any way without the slightest effort at resistance or escape. The nervous debility and torpor are not confined to the voluntary muscles, but all the organic functions are largely impaired, the bowels in particular are obstinately constipated, and when death ensues it is by asthenia.

"The milder cases, those even that present no appreciable
symptoms when at rest, are seized with trembling when made to undergo the slightest exertion, assume a very haggard appearance, drag their limbs slowly and stiffly, and after a drive of four or five miles will often suddenly drop down dead.

"The prostration is even more marked in sheep, and in very many cases they seem to be quite unequal to the task of rising."

"In vomiting animals, emesis is a prominent symptom. Calfes tremble while sucking, and often stop suddenly, eject the contents of their stomachs, fall to the ground, and perish. In pigs and dogs, vomiting and constipation are prominent symptoms; swine burrow under their litter, and are roused with difficulty, and dogs get 'the slows,' and are unable to follow their master. The result of exertion is the same in all."

"Convalescence in this disease is as peculiar as any other feature in its clinical history; and to this peculiarity I would invite especial attention, inasmuch as these facts are important in the study of its special pathology. Convalescence is rarely marked by a critical evacuation of any kind. I have no recollection, in any case, of a critical perspiration to mark the initiation of convalescence. A moist skin during the active stage of this disease, in my opinion, never occurs. Diuresis, or diarrhoea, as a rule, does not occur as a critical discharge. It is true a resumption of these functions occurs, but not in quantities to be regarded as critical. I have occasionally seen diarrhoea occur as a sequel, with typhoid symptoms; but I have always regarded it as a result of injurious use of drastic purgatives, or as evidence of uræmic poisoning from retained excreta. Ordinarily, convalescence is marked by a cessation of the characteristic symptoms, and a gradual resumption of the impaired and suspended functions,—only this and nothing more. There is a popular belief that a patient once suffering from this disease never fully recovers; and that, upon exposure to heat and fatigue, he is liable to a relapse. This, it is true, does occur occasionally, but not as a rule. On the contrary, I could point to scores of cases where recovery has been perfect and complete."—(Dr. Phillips.)

"Mr. Beardsley also testifies to the permanency of the effects, and liability to relapse in many cases.

"Lesions in Cattle.—Beside the presence of fungi in the blood, and the tendency to capillary stasis in different organs, the
following have been noticed:—'The stomach and intestines are inflamed (?) ; the mucous coat is measurably destroyed; the entire coats are in some cases gangrenous; they have a dark or black appearance, which is not due to a mere congestion; the coats are not firm, though they are not easily broken down. In the ventriculus, or paunch, and indeed throughout the whole alimentary canal, is found a substance conglomerated and resembling cemented sawdust, in the shape of balls, somewhat elongated, and perfectly adherent to the coats of the digestive tubes.'—(Dr. Schmidt.)'—(Veterinary Journal, Sept. 1877.)
CHAPTER XXXVIII

SPORADIC DISEASES—continued.

(III.)—LOCAL DISEASES.

Local diseases are those which have their primary seat and origin in any one tissue, function, or organ. They are sporadic diseases, and are generally, but not always, associated with constitutional disturbance, which, however, depends upon, and is secondary to, the original local affection.

(A.) DISEASES OF THE NERVOUS SYSTEM.

EPILEPSY—CHOREA.

Compared with the nervous diseases of man, those which affect the lower animals are few and insignificant. This can be accounted for in a variety of ways, but more particularly by the absence of the higher mental functions in the lower animals, and "in the way of life," from their non-participation in the excitaments, pleasures, hopes, and fears, as well as in the indulgences of the human race.

There are certainly some instances of what might be considered aberrations of intellect or morbid fancies in the lower animals, more particularly in the dog, by which the docile become ferocious, the good-tempered extremely irritable, the intelligent stupid or listless.

Animals also vary in degree of mental power: some are sharp, intelligent, easily taught, possessed of good memories, and are capable of manifesting a great degree of affection to those around them; while others are dull, hard to teach, have bad memories, and seem to live for themselves only. Notwith-
standing these varieties in the temperament and intelligence of animals, the purely mental—psychological—diseases are absent in our patients.

**Epilepsy.**

A peculiar nervous state, difficult to define, but in which complete loss of consciousness prevails for a short time, associated with spasmodic contractions of the muscles, succeeded by debility, and sometimes by a desire to sleep. Epilepsy occurs amongst all animals, but is most commonly seen in young dogs.

The pathological condition of the brain which gives rise to epileptic fits is not yet determined; indeed, in fifteen out of twenty cases in which the brains of epileptic human patients have been examined, the structure of the brain has been found quite healthy. Occasionally, however, the brain and its membranes are actually diseased; thus the membranes may be found thickened, inflamed, or even ossified. In one horse, subject to epileptic fits, an abscess in the white matter of each hemisphere was found by me; in another, tumours in the choroid plexus; but in some instances it is due to some condition of the blood, as in those fits which are associated with catarrhal fever. In young dogs epileptic fits are associated with dentition, and with worms in the intestinal canal or stomach.

Dr. Brown Sequard's researches into the origin of epilepsy are quoted at length by Mr. Gamgee in his *Domestic Animals in Health and Disease*, page 458. They are very interesting, but the tendency at present is to consider epilepsy certainly as a brain disease, but as one in which no definite pathological condition can in all cases be determined; and that the loss of consciousness, associated with excessive mobility, leads observers to regard those parts of the brain in the immediate vicinity of the *cella turcica* and basilar portion of the occipital region—for example, the central ganglia or medulla oblongata—as parts where, in future, morbid anatomy may yet discover a lesion.

**Symptoms.**—An animal in apparent health is seen to stagger and stare—the dog cries out at first, but is afterwards quite dumb—and then to fall into more or less violent convulsions, the whole system being agitated. The urine and faeces are sometimes passed involuntarily, the eyelids are closed, and if they are opened and the eyes examined, they will be seen to be in-
jected, sometimes convulsively agitated, at other times in a condition of strabismus (squinting), and sometimes fixed. During the fit the pulse is frequent, hard, sometimes intermittent, at other times scarcely perceptible; the respiration is stertorous, and sweats bedew the body.

I have carefully studied epilepsy, and have concluded that the condition termed vertigo or megrim is separate and distinct from what may be designated epilepsy, which is a disease, functional or otherwise, arising from extrinsic or intrinsic nervous irritation; whereas megrim is a term applied to all diseases which are associated with periods of insensibility or convulsions. I therefore limit the term epilepsy to a nervous affection characterised by convulsions, and which may appear either in the stable, kennel, or outside, at exercise or rest; whilst vertigo is applicable to a condition of syncope arising from disease of the heart or pericardium, and which occurs whilst the animal is at work or exercise. The epileptic subject, especially the horse, may be occasionally recognised whilst the animal is perfectly quiet, by a shaking of the head, and a working backwards and forwards of the ears, also by an occasional vacant, upward stare. This shaking of the head must not be confounded with that caused by ill-fitting bridles and head-stalls. Some horses are peculiarly square on the upper portion of the sides of the neck, and it will often be found that the borders of the neck are chafed by the head-gear. This should be carefully looked to before an opinion is given as to the soundness or unsoundness of a horse that shakes its head.

Treatment of Epilepsy.—If the fits are due to eccentric or peripheral causes—for example, to teething, worms in the stomach or intestinal canal, or indigestion, and this is not an infrequent cause—the first thing to be done is to remove these sources of irritation, by lancing the gums, extraction of offending teeth, and, by the use of vermilifuges and purgatives, expel worms or other intestinal irritants.

If the fits are due to disease of the nervous centres, all causes which may induce excitement or congestion of them are to be avoided; the food must be light and digestible, and the intestinal track cleared by means of purgatives, whilst the congestion, or a tendency to it, of the medulla oblongata and brain is best prevented or overcome by extract of belladonna. In the dog,
intrinsic epilepsy has sometimes given way to the salts of silver, zinc, or iron.

CHOREA.

Definition.—In the dog, a series of automatic movements of the head and neck, due to irregular convulsive action of the voluntary muscles. In the horse, the irregularity of action is generally confined to the posterior extremities (see Principles and Practice of Veterinary Surgery, Article Chorea), but it is occasionally seen affecting the muscles of the fore extremities.

The pathological conditions which give origin to the peculiar twitching or convulsive action of the muscles, characteristic of chorea or St. Vitus' dance, are not exactly determined, many pathologists who have investigated cases of the disease having failed to detect any definite morbid appearances. Consequently it has been regarded as an entirely functional disease, or as a disease due to an altered condition of the blood, the precise nature of such alteration not being known, and also as a symptom of some diseases of the heart.

In the dog, it may with good reason be said to be due to an altered condition of the blood, generally brought about by, or giving origin to, the disease called distemper, of which it is so often a distinguishing feature; whilst in the horse, spasmotic contractions of the thoracic and cervical muscles, of the nature of chorea, are often associated with cardiac diseases of a rheumatic type.

Symptoms in the Dog.—The convulsions may be confined to one fore leg or shoulder, of which there is a peculiar jerking action, like a series of pulsations. At other times both fore legs are affected, when there is a nodding or depressing of the head and neck. In many cases it is restricted to a constant jerking of the head and lower jaw, with marked twitchings of the superior cervical muscles; the muscles of the eyelids, and sometimes the muscles of the eye itself, are also affected. The convulsions do not cease whilst the animal is lying down, but they generally, although not uniformly, cease during sleep. In some cases the dog will remain otherwise healthy for an indefinite period; but if the chorea attacks it whilst in a debilitated state, the expenditure of muscular action, and the general restlessness, slowly undermine the remaining strength; the dog becomes emaciated, subject to fits, and finally paralysis and death supervene.
Sporadic Diseases.

The post mortem appearances are very indefinite. If succeeding a recent attack of "distemper," redness and softening of the spinal cord, meningeal dropsy, and in some cases spots of congestion on the medulla, optic thalami, and corpora striata, are discoverable; whilst in cases which have become chronic no lesions have been discoverable after death. Most probably, however, some change has taken place in the composition of the nervous system, which has not been detected; and this supposition is supported by the evidence that in acute or recent cases morbid changes are usually detectable.

In the horse, chorea may usually be regarded as a concomitant of other diseases, and will be mentioned in its proper place. In some cases the disease disappears spontaneously, more especially if mild and the patient be moderately strong.

Treatment in the Dog.—Attention to the condition of the bowels, removal of all sources of irritation by mild purgatives, generous diet, and tonics.

In human medicine, Dr. Walsha recommends the extract of cannabis indica as the most efficacious remedy, in doses of one-fourth of a grain thrice daily. In other cases much benefit has accrued from the cold bath. In my own practice I have found that camphor and spirits of nitrous ether are sometimes very useful, allaying the restlessness and diminishing the convulsions. At the same time the animal strength has been improved by good food and sulphate of iron. I find that the best diet for dogs is milk and oatmeal porridge in the morning, and an allowance of flesh, according to size, in the evening.

The foregoing diseases not being essentially due to inflammation, congestion, or organic alteration of any particular part of the cerebro-spinal system, I have placed them under the general head of "Diseases of the Nervous System." Having done this, I now purpose giving a detailed description of those nervous diseases to which a locality can, with some certainty, be ascribed.
CHAPTER XXXIX.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(B) CEPHALIC DISEASES.

INFLAMMATION OF THE BRAIN SUBSTANCE—CEREBRITIS.

This is a very rare affection, and its occurrence can only be proved by post mortem examinations. Mr. Gangee says that it is impossible in practice to distinguish between inflammation of the brain—cerebritis, and inflammation of its coverings—meningitis. In this he is so far correct; but pure cerebritis does occur, if we are to look upon the formation of abscesses in the white substance of the cerebrum as evidences of inflammation.

I have seen two cases which presented this appearance post mortem, and another, that had all the symptoms of cerebral abscess, and recovered, but was peculiar in its motions and action, had epileptic fits, was unable to back, turned with difficulty, and moved its limbs automatically as long as it lived.

The three cases mentioned were suffering, or were recovering from strangles, the advent of the brain symptoms succeeding to the formation of the abscesses in the intermaxillary space. In the two that died, the symptoms were, great drowsiness, slowness of the pulse, inability to masticate food, although a desire to eat still remained, staggering gait, dragging of the feet, and subsequently coma, with stertorous breathing, amaurosis, paralysis, embracing the muscles of the head, trunk, and extremities, rapid sinking, and death. In one case the voluntary muscles were quite flaccid, and were incapable of any movement; whilst in the other some contractile power still remained, and now and then feeble struggling would take place. It was able to move
the limbs, but very slightly, and possessed a little sensibility when pricked with a pin. In both cases the sphincters were relaxed, and urine flowed involuntarily.

In the third case—the one which lived—the symptoms were those of incomplete paralysis of the whole muscular system; there was drooping of the lips, semi-closure of the eyelids, staggering gait, automatic muscular movements, and when the horse was moved, muscular action continued for some time. When its head was pressed against a solid object, such as the walls of the stable, it would continue to move its limbs, and press its head and body forward with great force; indeed there seemed to be a tendency to go straight forward. The desire for food was pretty good, and although mastication and deglutition were performed with difficulty, it was able to take a fair amount of support, consisting of milk, eggs, gruel, &c., in addition to ordinary food. It continued in this condition for about fourteen days, when it burst through the box door during the night of 31st December 1862, and was found prostrate, and covered with snow, in my yard in Bradford, when the groom went into the yard on the morning of 1st January; it was immediately dragged into its box, and covered over with clothing and straw. It lay prostrate, steaming with perspiration, thus induced, for three days, during which time it scarcely moved. As the bowels were constipated, a full cathartic was given, which responded on the second day; the urine flowed involuntarily, doing away with the necessity of using the catheter. On the third morning some degree of consciousness returned, and it was now able to drink water—small quantities of which had been carefully given it out of a bottle—and in the evening it rose to its feet. It now gradually recovered, but ever afterwards showed some degree of aberration of mental powers—"intellect," if the term is proper—and was always called the "cranky horse" by the men about it. I conclude that this was a case of small abscess in the cerebral substance, from the fact that it was at the time affected with a pyogenic disease—strangles—and from the similarity of the symptoms to those seen in the cases in which I had the opportunity of making post mortem examinations; and I account for the partial recovery on the supposition that the pus had either broken down and was absorbed, or had become insipidated, and the medullary tissue of the brain accommodated to its presence.
CEREBRITIS.

The differences between cerebral and meningeal diseases are arranged as follows by Aitken, and as, to some extent, they may prove useful in diagnosis, I take the liberty of quoting them:

CEREBRAL DISEASE.

1. From the outset, or from a very early stage of development, there is loss of some one or more of the proper nervous functions, such as paralysis, anesthesia, loss of memory.

2. Cerebral disease is not commonly attended by high-marked exaggeration of function, such as furious delirium, convulsions, intense hyperesthesia, or tenderness.

3. Little vascular excitement attends cerebral disease, nor is there frequently any highly marked general disturbance.

MENINGEAL DISEASE.

1. It is not till some time after the detection of signs of disease that diminution or loss of nervous function takes place.

2. The subsequent diminution or loss of nervous function which succeeds the prolonged existence of "head symptoms" is generally preceded in cases of meningeal disease by extremely severe excitement or exaggeration of functions, such as pain, tenderness, furious delirium, or convulsions.

3. In meningeal affections there is usually much local vascular excitement, with general disturbance.

4. Spasms, or convulsions, pain, and delirium are the general features of meningeal disease.

In all the three cases of cerebral abscess mentioned, there was the absence of the above-mentioned indications of meningeal disease; and indeed the post mortem of the two fatal ones proved this, and even the automatic movements of the limbs of the third case clearly proved that volition was to a great extent destroyed.

In each of the brains examined, the abscesses were symmetrical, situated in the anterior lobes of each hemisphere, and were seen, after the removal of the dura mater, as two bulging prominences, measuring about an inch in diameter, which, when opened, gave exit to a thick, whitish pus, of good consistence and free from smell. The walls of the abscesses consisted of the
medullary substance, covered here and there in one case with small red points; whilst in the other the surrounding substance was of the natural colour.

TREATMENT.

But little can be suggested in the way of remedial treatment. If the animal lives sufficiently long, the liquor puris may be absorbed, and the shrivelled pus cells remain, as in the case recorded. But little assistance can be given to this, beyond keeping the bowels open by an occasional cathartic, to act as a derivative, and attending to the diet of the animal; the food in all instances must be nutritious but non-stimulating. Care must also be taken that the animal does not injure itself by falling; and to prevent injury to the head, some soft substance, such as a sack stuffed with straw, should be placed in front of the patient, in order that it may rest its forehead upon it.
CHAPTER XL.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(C.) ENCEPHALITIS, INFLAMMATION OF THE BRAIN AND MEMBRANES—CEREBRO-MENINGITIS, PHREMITIS, MAD STAGGERS, PHRENZY, COMA, SLEEPY STAGGERS, STOMACH STAGGERS, ABDOMINAL VERTIGO, &c.

Definition.—A morbid condition of the brain and its membranes, attended with congestion of the vessels, effusion into the ventricles and subarachnoid space, with exudation of lymph between the convolutions, and arachnoid and pia mater.

Percivall, Blaine, Dick, and others describe two forms of staggers—the one arising from inflammation of the encephalon, and the other from engorgement of the stomach, respectively denominated "mad" and "stomach staggers;" and we are led to conclude that in the latter disease the brain is only sympathetically affected, or is disturbed by reflex irritation. Mr. Gamgee says, "I regard phrenitis as almost an unknown disease." If by this Mr. Gamgee means the phrenzy or mad staggers of our forefathers, experience compels me to agree with him; but if he intends to convey the idea that encephalitis, or inflammation of the brain and its membranes, occurs as a traumatic disease only, I am bound, by the same experience, to differ from him, as experience amongst the living, and examinations of the dead subject, have convinced me that the conditions named "mad," when not caused by violence, traumatically, or by tumours, &c., and "stomach staggers," are symptomatik of but one and the same malady, namely, inflammation of the brain and its meninges, and that the varying degrees of violence, convulsions, frenzy,
stupor, coma, immobility, or paralysis, depend upon the seat of the congestion or inflammation at the time such symptoms are manifest. For example, the coma and loss of function become apparent when the brain proper is congested, or when pressed upon by effusion; the convulsions, tetanic spasms, and frenzy when the pressure is not so great, and when, in all probability, the membranes are the seat of the congestion or irritation; and paralysis of a part of the body, generally the posterior extremities, when there is inflammation of the spinal cord and its membranes.

There are many pathological conditions of the brain which give rise to symptoms of frenzy, such as tumours, some non-cognizable morbid poisons, uremic poisoning, rabies, the irritation of melanic deposits, &c.; but inflammation gives rise to loss of function, and instead of the exalted condition, so graphically described by Percivall, we have in true cerebritis stupor, coma, and general paralysis.

Mr. Ga jeep describes a form of encephalitis in horned cattle arising from alcoholism. The cases are reported by Mr. George Dundas in the Edinburgh Veterinary Review. "The disease is due to a practice, prevalent in some parts of Scotland, of giving "burnt ale" to cows, in the neighbourhood of distilleries. The ale is given by steeping straw in it; and the animals will also drink it freely. They often sleep soundly after such a beverage, and sometimes symptoms of intoxication are manifest. The symptoms are as follows:—The head is turned singularly to the side, and is slightly elevated. The pupils are widely dilated, and the eyes have a remarkably wild appearance. On approaching the animals, they wink rapidly, and tremble. There is marked heat of head, horns, and ears. When pressed with the finger in the axilla they fall instantly, and when pulled by the head they incline to turn over. The pulse is about seventy or eighty per minute."

"After death, all the organs are found healthy except the nervous centres, and both brain and its membranes are found congested. This congestion often extends into the spinal canal, and the pia mater over both the brain and cord is the seat of red spots. The redness is either ramified, or is obviously due to blood extravasation. Clots of blood have been found in the lateral ventricles, and around the spinal marrow in the cervical
regions. There is evidently softening of the brain substance as a direct result of this condition."—(GAMGEE'S Domestic Animals in Health and Disease.) I have never witnessed this effect of alcohol on cattle, although I am familiar with the fact that the "dreg" from distilleries is largely used for feeding purposes, and that it is an excellent adjunct to other foods.

The most common form of congestion of the brain and its membranes, both in the horse and horned cattle, is that called stomach staggers, sleepy staggers, or grass staggers—a disease which sometimes rages as an enzootic.

**SYMPTOMS.**

The animal at first appears dull, listless, falls asleep whilst standing, or drowsily nods its head; eats slowly and at intervals; the breathing is generally slower than is natural, sometimes slightly accelerated, but it is always of a somewhat snoring description. The pulse is also slower than natural, from twenty-six to thirty, full and rolling. When made to walk, it has a straggling gait, staggers, and seems as if about to fall. If suddenly disturbed whilst in the somnolent condition, it looks around excitedly, shivers violently, and seems affrighted; but soon becomes calm again, and may remain so for a short period, especially if kept in a dark, quiet place. It now and then thrusts its head against the rack or wall of the stable; moves the limbs automatically; rears, hangs back, and breaks the halter, or gets its fore feet into the manger, and elevates the nose high up into the rack. The eyes, mouth, and rectum are injected, and of a yellow tinge. In some cases, the yellowness of the mucous membranes is a very prominent symptom. As the disease advances, the extremities become alternately hot and cold; sweats bedew the body; there will be twitchings or clonic spasms of the superficial muscles of the neck, breast, and hind quarters. Violent convulsions will now occur; the whole body becoming stiff and rigid, and the respiratory movements extremely difficult. During these spasmodic—tonic—attacks, the tail will be elevated, the membra posteriors drawn over the eye, as if the animal were suffering from tetanus, and the pulse frequent, hard, and wiry, the eyes fixed and amaurotic, the mouth clammy, and the urine may be ejected by a convulsive
effort. All at once the tonic contractions subside, and there will be great muscular debility; the legs bend, the animal totters, sometimes falls, and when down will fight convulsively, and for a time be unable to rise. By slow degrees consciousness to some extent returns; the animal may then regain its feet, and will perhaps commence to feed; then fall asleep, with its mouth full of food, or look about in a wild, staring, vacant manner, or ramble unconsciously about the box, striking its head against everything that may come in the way, the eyes amaurotic, and the animal quite blind.

Sometimes there is flaccidity or paralysis of the muscles supplied by the cranial nerves, the lips are pendulous, and the tongue hangs out of the mouth. At other times there will be tonic spasm of the facial and masticatory muscles, and some degree of trismus present.

The disease may attack the animal whilst at grass in the field. It is then observed to ramble about in an unconscious, drowsy manner, until it meets with some solid object, against which it fixes its head, and then moves its limbs continuously.

In cases which have been noticed at the commencement of the attack, some degree of rigor has always been observed premonitory to the development of other symptoms.

The above symptoms are subject to some variations. In some animals the comatose and paralytic conditions are the most prominent throughout, whilst in others delirium, convulsions, and spasmodic contractions alternate with the stupor. In other cases, again, the spinal system seems most affected when paralysis, without loss of consciousness, or with but a slight degree of drowsiness, is present.

There appears to be a general diminution of the various secretions; the constiveness is obstinate; the urine is secreted in small quantities, and is particularly high in colour. The function of the liver is also suspended, and the whole system becomes tinged with the non-excreted biliary colouring matter—biliverdine.

As the disease advances the coma is more profound, or the fits of excitement and frenzy more frequent, and of shorter duration, leaving the animal more and more enfeebled; the pulse is now small and quick, and the breathing stertorous and difficult; profuse sweats bathe the body, the sphincters relax, the
animal is unable to stand, and dies fighting convulsively, or in a state of profound coma.

**ETIOLOGY.**

It is very generally held by writers upon veterinary medicine that the malady arises from an over-loaded and impacted condition of the stomach, that the cerebral symptoms are purely reflex or sympathetic, and that no actual disease of the brain or its meninges is present. These assertions are not supported by the results of investigation into the morbid anatomy of the malady, further than that the stomach has been generally found filled with food. Now, if engorgement of the stomach were the cause of the train of symptoms seen in this malady, then coma, delirium, or paralysis would be general in the majority of cases of engorgement, seen in the routine of general practice, but this is not the case. Numerous instances of engorgement, impaction, even to rupture of the stomach, constantly come under the notice of the practitioner, but signs of any brain affection scarcely ever occur. We must then look to something more than mere impaction as the cause, and I think this will be found in the nature of the food.

In Scotland it has been called "grass staggers," from the fact that it occurs when the animal is fed on green food; but ordinary green food does not induce it. I have very carefully noted every case which has fallen under my care for some years, and I find that grass, more particularly rye-grass, when it has commenced to ripen, or when it has been cut, and allowed to heat and ferment before being used, is a fruitful source of this disease. I find that my observations are borne out by those of Professor Dick and others, and that not only horses and cattle are liable to the disease from this cause, but sheep, and especially lambs.

Mr. Brydon, V.S., Tranquair, in a letter to Professor Dick, says that lambs are often destroyed by eating the tops of rye-grass; and that he has found the tops of rye-grass two or three inches in length in their stomachs, causing inflammation.

Professor Dick again says—"From what has been stated it will appear that, when rye-grass begins to ripen, a change should be made in the food by placing the animals on other pasture. The grass should be cut before it has quite ripened, as it will be found in that state innocuous." He then refers to a statement made
by White of Exeter, in White's *Farriery*, that the disease occurred in one farm in South Wales, from hay made the previous year (1800), and concludes that "it seems more than probable the hay had been over-ripe when made, and that the process of withering had not destroyed the irritating or noxious, or perhaps narcotic, quality of the over-ripe grasses."—(Veterinary Papers by Professor Dick.)

I quite agree with Professor Dick that the disease is due to some peculiar narcotic principle, that is developed in the grass at this time, or which may be developed by the process of heating and fermentation, when cut at an earlier stage of its growth; for every-day experience proves to us that food, even rye-grass included, has no effect in producing symptoms of cerebral disturbance, when used in its ordinary condition, and that it is only when in a transition stage, as it were, between grass and hay, that it seems to possess toxic qualities.

After careful observation I have arrived at the conclusion that the seat of this disease is in the brain, the spinal cord, and their meninges; that, owing to the quality of the food, a degree of narcotism is first produced, speedily succeeded by congestion and other changes to be described in the morbid anatomy, and that owing to this derangement of the great nervous centres, paralysis of the digestive apparatus is the result, and the stomach becomes sometimes engorged, from the fact that the animal continues to feed, when the digestive as well as other functions are in abeyance.

This disease seems to have first attracted notice in 1787, the summer of which was hot and dry. It raged in the south-west of England and Wales in 1800 and 1819, the summers of which were also hot and dry, prevailing most commonly amongst horses at grass in low, wet pastures, where the grass was rank. It was supposed to arise from their eating ragwort or stagger-wort—*Senecio Jacobaea*—a plant supposed to contain a poisonous principle, or some other poisonous herb; but of this there is no absolute proof. We have, however, sufficient evidence to prove that it originates when animals eat rye-grass in the condition described. Mr. Gaungee says the disease may arise from gastric derangement, brought about by eating wheat, or even oats and bran, in large quantities. My experience convinces me that this is not the case, and that mere over-loading is more apt to pro-
duce rupture, tympanitis, inflammation of the bowels or feet, or intestinal apoplexy.

MORBID ANATOMY.

From various dissections, very carefully made, it is found that impaction of the stomach is but an occasional complication. In many cases some degree of congestion of the villous coat has been present, and this appearance led Blaine to conclude that the disease was a specific form of gastritis; but this is not an invariable lesion, and is most probably as much induced by the action of medicinal agents as by food. The stomach may be quite empty; sometimes it contains some amount of food, and at other times it is impacted; there is always a congested condition of the lungs, as is the case in death by coma. The brain and its membranes are invariably congested; the former, after removal, seems to be in a swollen condition; the dura mater seems stretched, and the convolutions appear broader and flatter than natural, as if they had been pressed against the cranial walls. The vessels of the pia mater are injected and tortuous, and that membrane itself is easily lacerable, and may be stripped from the surface of the convolutions without tearing the cortical substance, which of itself looks darker than natural. On cutting into the brain both grey and white matters are studded here and there with red points. The plexus choroides is large, highly injected, sometimes covered with a thin film of exudation, and the lateral ventricles are filled with fluid.

In the spinal form of the disease, namely, that characterised by paralysis of the hind extremities, the congestion and effusion are generally limited to the spinal cord and its membranes in the dorso-lumbar region; the arachnoid space is filled with serosity of a reddish colour; the pia mater is congested, and the cord itself in a red, softened condition.

Prognosis.—In the horse the probabilities of recovery are much greater than in oxen and sheep, in which it is very fatal. The recovery in the horse, however, has been slow and protracted, some degree of paralysis in many cases remaining for several weeks after the acute symptoms have passed off. Recovery may be expected when the symptoms do not become much aggravated during the first day or two, when the delirium is not excessive, and when the coma is not continuous and profound. In the
spinal form the animal may fall and be unable to rise, very early in the disease; this is but of little moment, provided the animal does not struggle much, and work itself into a state of fever and exhaustion. In the cerebral form, inability to retain the standing posture is always a bad sign, more especially if the delirium be continuous. The age of the animal must also be taken into consideration; the young and strong may recover, the old and debilitated succumb.

TREATMENT.

In the early stages, when the pulse is full, and has tone, bleeding has a beneficial effect, by directly unloading the vessels of the brain. Indeed, I have witnessed most marked results from this, the almost unconscious, amaurotic animal regaining its sight and consciousness in a short time. Four, five, six, or even eight quarts can be taken from the jugular with advantage. If, on the contrary, the pulse be feeble, accelerated, as in the later stages of the disease, bleeding only hastens the animal’s death. A smart cathartic is always to be administered, and no danger need be apprehended from superpurgation. The purge may be composed of from six to eight drachms of aloes, and a drachm of calomel for the horse; twenty ounces of sulphate of magnesia, and fifteen croton beans for a full-sized ox or cow; after which the animal is to be kept as quiet as possible; all food must be removed; plenty of water allowed to drink; an enema now and then administered; and the head bathed with cold water. The attendant is to do all this quietly and calmly; there must be no shouting, or any noise to disturb the animal, nor is it to be continually dosed with medicine. Time must be allowed for the purgative to act, and in some cases there is no response for two or three days; but if the symptoms abate, no alarm need be felt, as the bowels are always slow to act when in a paralyzed condition. Should the symptoms increase in severity, belladonna might be tried, in two-drachm doses of the extract, or two grains of atropine injected subcutaneously twice a day.

I would, however, prefer trusting to the purgative, which is to be repeated in smaller quantity on the third day, if the bowels are not responding freely.
When the acute symptoms have passed off, it may be necessary to apply blisters to the loins, or at the back of the poll; but during the earlier stages, more especially if the horse is restless, nothing should be done to irritate and annoy it, or it may work itself into a state of excitement which speedily terminates in death. In addition to blisters, I have found the iodide of potassium, given twice a day, to be exceedingly useful in promoting the absorption of any exudate or effusion; and should the bowels remain torpid, and an imperfect paralysis continue, nux vomica may be added with advantage. It may be here remarked that the arrestation of the urinary, biliary, and intestinal secretions are results of cerebral disturbance, and that when this is removed the secretions regain their natural condition. Purgatives are useful as removers of the cause, which is food containing deleterious principles, and as derivatives. If the pulse be feeble, small doses of stimulants—ammonia—may be administered. I am, however, no advocate for large doses of stimulants, as they tend to excite the animal and make it restless, when quietude is of the greatest importance.
CHAPTER XLI.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(D.) CEREBRAL APOPLEXY.

Definition.—"A disease essentially characterised by the sudden loss, more or less complete, of volition, perception, sensation, and motion, depending on sudden pressure upon the brain (the tissue of which may be morbid), originating within the cranium."—(Aitken.)

Apoplexy is of two kinds:—1st. That arising from degeneration of the cerebral vessels, with rupture of them, and extravasation of blood upon or within the substance of the brain; and 2d. That in which congestion of the cerebral vessels—not of themselves necessarily diseased—is the primary condition; this, when excessive, resulting in rupture and extravasation.

SEMIOLOGY.

Apoplexy from the rupture of degenerated blood-vessels.—There may be some premonitory symptoms, such as staggering and partial paralysis, but generally the animal falls suddenly without warning. After falling it may lie prostrate, in a state of unconsciousness, without the power of voluntary motion, perfectly insensible to surrounding objects, and dead to all ordinary feeling, with its eyes wide open and presenting a ghastly stare, the pupils dilated and insensitive to the light—amaurotic. The breathing is stertorous, the pulse small, rapid, and thready, the surface of the body cold, or bedewed with a cold sweat, the limbs flaccid, the mouth open, and filled with frothy saliva, and in some severe cases the sphincters are relaxed. In other
instances the animal may still retain the power of muscular movements; but they are irregular, and intermixed with spasmodic contractions. Whilst down, it fights convulsively, presses the back of its head violently against the wall or other solid body. Some degree of opisthotonos is present, the back is arched downwards, and the hind legs extended backwards. The eyes move about convulsively, or there may be persistent strabismus of one or both of them; the pupils may be dilated or contracted, alternately contracted and dilated, or they may be natural, or one may be contracted, and the other natural or even dilated. The respiratory movements are sometimes spasmodic; now and then there may be a stertorous sound; at other times sighing, and sometimes expressions of great pain, as if the animal had been sharply wounded with a cutting instrument.

These symptoms may alternate with intervals of quietude, when the animal will fall into the comatose condition. The pulse may then fall below its natural standard, and the respiratory movements may become slower than natural, with heavy, deep inspirations. The various secretions are, in all cases, suspended, and the animal gradually sinks from increasing brain pressure, or suddenly from renewed extravasation.

The symptoms of apoplexy present some degree of variety in their character, and in the course of experience one cannot but remark that conditions which were laid down by our teachers as being invariably present, are sometimes altogether absent, or are present in a very modified degree. For example, it is generally taught that when a patient is apoplectic and comatose, the pupils are widely dilated, and the eyes amaurotic; but this is not always the case, neither is contraction of the pupils an invariable sign of brain disease. In many cases the condition of the eyes is quite normal. Again, the loss of consciousness varies very much; in one case we have complete insensibility, in another a degree of hyperesthesia to touch and sound, as expressed by convulsions and tremors, when the animal is touched or spoken to. In one case, although a large clot, extending from the superior surfaces of the crura to the base of the brain was discovered post mortem, it was observed that when left alone the horse would lie more or less quietly; immediately it was disturbed it would fight convulsively, the breathing would become spasmodic, and it would dash its head with
violence upon the ground; when pricked with a pin it showed extreme agony.

Stertorous breathing.—This symptom, like the other, is not invariably present, indeed it is often absent in undoubted apoplexy. At all times it indicates severe lesion, and that the pons varolii or medulla oblongata are implicated.

MORBID ANATOMY.

Apoplexy from degeneration is seen in old horses, in which the post mortem examination reveals the cerebral arteries in an atheromatous condition. The first attack generally proves fatal, but I have seen two cases of relapsing apoplexy, in which distinct post mortem traces of former extravasation were found.

The clots are either superficial or deep seated. Superficial clots are generally supposed to be due to external violence. This is, however, not always the case. Extravasations are found in the lateral ventricles, from a rent in the corpus striatum, or from rupture of some of the vessels of the choroid plexus, upon the surface of the cerebrum, and at the base of the brain; in one instance there was, in addition to a tumour, extravasation from degeneration and rupture of the vessels of the falx cerebelli.

The extravasations are occasionally circumscribed, but most commonly diffused, and spread over a more or less extensive surface, extending from the lateral to the fourth ventricle, and sometimes surrounding the crura cerebri.

In rare instances the symptoms may take some days before they become fully developed. This is due to very slight but increasing hemorrhage. In the majority of cases the attack is sudden, and the loss of power almost instantaneous. Congestion of the brain—as in the last described disease—occasionally terminates in apoplexy, or rupture of the cerebral vessels and extravasation of blood; but congestive cerebral apoplexy is a rare disease in the horse, that which is usually met with being due to degeneration of the vessels.
CHAPTER XLII.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(E.) APOPLEXY FROM CONGESTION.

This form of apoplexy, except as a sequel to encephalitis, is very rare in the horse, but is of frequent occurrence in cows, and is variously termed parturient apoplexy, milk fever, dropping after calving.

Definition.—A parturient disease, characterised by suppression of the lacteal secretion, congestion of the brain, and apoplexy.

ETIOLOGY.

Various opinions are held upon the causes and origin of parturient apoplexy, some writers maintaining that it is a blood disease, whilst others state that conformation or anatomical peculiarity is sufficient to account for its occurrence in the cow, and its absence in the mare. The late Mr. Barlow, in a most profound and remarkable paper, traced its origin to derangement of the great sympathetic nerve, with consequent arrest of secretion, resulting in general congestion, which became localized in the brain and spinal cord; whilst other observers express an opinion that the disease results from derangement of the digestive apparatus, and that it is a peculiar form of indigestion.

Without entering into a critical examination of these various hypotheses, I may venture to state that there is no evidence of the primary presence of a blood poison. Mr. Gamgee ventures upon the assertion "that notwithstanding the sporadic nature of parturient apoplexy, in cattle it is marked by the development of a poison capable of inducing a similar disease in other animals,
of affecting the human frame, and hence of rendering the flesh of animals affected by it unfit for human food."—(Domestic Animals.) If this assertion were correct, the number of the human race would, ere this have been much reduced, for it is a well-known fact that the flesh of cows slaughtered whilst suffering from parturient apoplexy is a common article of diet, and that no bad consequences result from it, provided the animal has been slaughtered early, before the system has been empoisoned by the excessive doses of medicines which are so generally prescribed in this malady, and antecedent to a general vitiation of the animal solids and fluids by the accumulation of effete materials.

The anatomical theory is upset by the fact that the disease is inseparable from domestication and stimulating food; peculiar to deep milkers, and scarcely ever succeeding difficult parturition, which most assuredly would be the case if shortness of neck, excessive—natural—vascularity of the brain and its membranes were predisposing causes.

The other theories, namely, that which traces the origin of the disease to derangement of the function of the ganglionic or sympathetic nerve, and that ascribing it to indigestion, may conjointly, I think, be looked upon as offering at least an explanation.

Parturient apoplexy rarely occurs prior to the third period of parturition, but I have seen it, in two instances, succeed the second calving. Cows of all breeds are subject to it, provided they are deep milkers. It seldom attacks cows in which the lactiferous system is not highly developed, no matter of what breed they be. Age, and the profitable property of giving an abundant quantity of milk, are acknowledged and well-known predisposing causes; so much so, that dairymen very often decline to buy a deep milker immediately prior to a third or subsequent parturition. This tendency to the malady is promoted and intensified by warm weather and stimulating food, which is generally allowed in great abundance. All cows, but more particularly those which are profitable milkers, ought to be well fed; but it should be remembered that prior to the act of parturition, deep-milking cows, which are dry or nearly so, rapidly become plethoric, and that this state of body, at the time when the calf is born, is one which very commonly excites
this fatal malady; hence, in feeding an animal of this kind, great care should be taken that the food be not over-abundant, too highly nitrogenous, or too watery. A previous attack of parturient apoplexy also predisposes to a second, and generally fatal attack of the malady.

The exciting causes may be looked for in the act of parturition itself, mistake in the dietary, and in the season of the year.

In rare instances, parturient apoplexy occurs during or immediately prior to the birth of the calf; but almost invariably the first symptoms are not manifested before the lapse of some hours—from twenty to twenty-four hours is a very critical period—or even two or three days after parturition.

When symptoms of the malady are not manifested for some time after the birth of the calf, it will generally be found that the secretion of the mammary gland has been in an average, or even abundant quantity, that the appetite has been good, and ruminating naturally performed. Premonitory to other symptoms, it is generally seen that the secretion of milk is suspended.

The arrest of the lactiferous secretion is doubtless due to some disturbance of the organic system of nerves, but how this arises it is difficult to determine, unless we take into consideration that the great sympathetic is developed to a greater extent in deep milkers than in other cattle, and that in consequence it is more susceptible, and more prone to derangement from trivial causes, especially at this critical period.

In the natural or healthy condition, the blood required for the support of the fetus in utero is diverted after the parturition into the mammary gland, for the purpose of supplying material for the formation of milk. One portion of the ganglionic system is thus brought into increased action, whilst that which during the pregnancy had been developed in the uterus, being no longer required, falls into a condition of at least temporary atrophy.

If we bear in mind that the blood required to support the fetus prior to its birth is diverted, as it were, in the healthy state to the mammary gland, when the mother is delivered, in order to supply material for the secretion of milk; and if, in addition to the arrest of the lactiferous secretion, the various excretory organs cease to perform their functions, it can be easily understood how the whole vascular system becomes preternaturally engorged or congested. Such then is the condition
of the system in this affection, not only prior to the occurrence of
the local cerebral congestion, but throughout its course, and
after the animal’s death, when the vessels are found engorged
and the tissues loaded with effusion.

I think that the particular congestion of the brain and its
meninges is determined by the state of mental excitement
which is always present at this period, and this argument is
borne out by the fact that the removal of the offspring from its
mother is a fruitful exciting cause of the so-called milk fever.
That the lower animals are capable of expressing strong maternal
affection is patent to all observers. Who has failed to witness the
restlessness, loss of appetite, and unhappiness of many a cow de-
prived of its calf? and this is a fruitful source of derangement
of health.

To exemplify this, a case of general paralysis in a she-goat came
under my notice a short time ago, which I will here relate. The
goat’s kids, four weeks old, were taken away from it by
the owner, who, on returning in about an hour’s time, found the
poor animal completely paralyzed, moaning piteously, and evi-
dently in a state of great distress. It remained in this con-
dition for several days, when the owner brought it to the New
Veterinary College for my opinion. When I saw it, it was
quite conscious, but powerless, lying at full length upon its side.
I kept it for several days, but it gradually sank and died.
Now in this case there was no cause of disease but mental dis-
tress, and if this be the case with the goat, most assuredly mental
distress may be a cause of derangement in the cow. In addition
to the removal of the calf from the mother, it is a common
practice to make sudden and violent changes in the animal’s
diet. For the food to which it has been used, thin bran slops,
gruel, &c. are substituted: this of itself would be sufficient to
induce indigestion and serious constitutional disturbance.

That middle-aged animals are more prone to the malady is
explained by the facts that the lactiferous powers are greater in
them than in the young, and that the functions of the ganglionic
nerves are more active, and consequently are sooner deranged.

Atmospheric conditions have also to some extent an influence
in predisposing to the malady. During warm spring weather it
is much more prevalent than in cold seasons: from this cause
many newly calved cows are simultaneously attacked, leading
some to suppose the disease to be enzootic.
APoplexy from Congestion.

Semiology.

In many instances the symptoms appear suddenly, and with great violence, the disease running its course, and terminating fatally in a short period, but most commonly there are some premonitory signs. The secretion of milk is stopped, the cow hangs its head, ceases to feed, and paddles with its hind feet. By-and-by the breathing becomes hard and rapid; it sways from side to side; the hind legs double at the fetlocks, and at last it falls. The eyes are blood-shot, in some cases wild and staring; the eye-lids twitch spasmodically, and an abundant flow of tears runs over the cheeks. The ears, horns, and forehead are now intensely hot; the animal lies either in a state of perfect stupor or coma, or dashes itself violently about; the head is thrown from side to side, and there is danger of the horns being knocked off.

In some cases the nose rests firmly upon the ground, and if the head is lifted up, it will fall back like some lifeless body; at other times the head is brought back to the side, where it remains firmly pressed against the shoulder or neck. There is often a disposition to lie upon the side, in which case the neck is stretched out, and the limbs extended, the eyes glassy, and the mouth open; tympanitis soon sets in, and the cow will die in a very short time if its position be not altered. Very early in the disease the power of vision is lost, the eyes being amaurotic; the power of swallowing is also lost, or very imperfectly retained. The cow may remain in this condition for several hours, provided it is made to lie, by packing in the natural position on the sternum, evincing but few signs of life, except the act of breathing, which is generally stertorous; now and then there is emitted a gurgling sound of gas and fluid regurgitated from the rumen.

The pulse, which at first is generally full, and more or less accelerated, becomes small, quick, and almost imperceptible; the breathing is more and more difficult; in some cases convulsions set in, whilst in others death occurs from a gradual sinking of the vital powers; the sphincters are paralyzed, the mouth open, and the breathing partially oral, with puffing of the cheeks at every expiratory act.

In some instances the symptoms of delirium are very violent;
the animal struggles violently whilst down; works itself on to its side in spite of all precautions; dashes its head wildly about; bellows, groans, and strains violently; very shortly the abdomen becomes tympanitic, and the breathing more laboured and difficult; there is eructation of fetid gases from the rumen, and death rapidly supervenes.

In other cases consciousness in some degree returns, the eyes become natural, the cow pricks its ears as if it once more could hear sounds, the secretion of milk returns, the body cools, and seems as if convalescence were in reality established. These flattering signs are, however, too often succeeded by a return of the worst symptoms, and it very frequently succumbs.

In some instances the bowels may be relaxed in the earlier stages; and this will greatly depend upon the previous treatment of the animal. This is, however, very soon succeeded by non-excretion both of faeces and urine. Constipation, or rather non-passage of the faeces, is always a marked sign, not that there is any actual dryness or constiveness, but that the muscular walls of the intestines are in a paralysed condition, the peristaltic action being lost. The urine, generally pale in colour, and free from albumen, scantily secreted by the kidneys, is retained in the bladder, which has also lost its power of contractility.

PROGNOSIS.

I consider it a good sign, if, after the animal has fallen, it is able to rise, although it fall again, and become perfectly comatose. This conclusion is a result of experience, but I can offer no explanation of it. If in the course of thirty to forty hours consciousness gradually returns, and the animal makes attempts, but not too violent, to rise, the bowels commence to act, the secretion of milk, and a desire for food return, a successful termination, at least of the apoplexy, may reasonably be expected. If, on the contrary, the sphincters relax, the coma becomes more and more profound, or the delirium continue, and if, in addition to these, the dropping of the jaw and oral breathing, which are always indicative of grave lesions, become manifest, a fatal issue is to be expected.
POST MORTEM APPEARANCES.

The vessels of the body generally are filled with dark-coloured blood, the tissues are moist; the uterus is generally large and congested: this may, however, be unassociated with the disease, as it is the natural condition of the womb so soon after parturition. Extravasations of blood are found at the base of the brain, on the medulla, and cervical portion of the spinal cord. In some cases, however, actual rupture of the vessels has not occurred; great congestion of the vessels and the red points—puncta vasculosa—have been very marked when the brain has been cut with the knife, and in others no marked congestions have been seen, having in all probability disappeared post mortem, or perhaps immediately previous to the animal's death—congestion being generally an ephemeral condition; but in all instances there is an accumulation of fluid in the ventricles, and the brain substance itself is loaded with serosity.

The digestive organs, kidneys, liver, heart, present no special signs; the serous membranes are sometimes covered with petechial spots, the lungs are engorged as in all cases of death from paralysis of the respiratory apparatus. Thinking that perhaps the symptoms of intoxication seen in the disease were due to uræmic poisoning, I have very carefully examined the kidneys, but have never been able to detect any special lesions which support that view. It is quite possible, however, that urea is superabundantly present in the circulation, but I do not think that it has any special connection with the origin of parturient apoplexy. Further observations are, however, required before this matter is satisfactorily solved. I have never detected albumen in the urine.

TREATMENT.

In the earlier stages, whether the animal is standing, or lying prostrate and in a state of coma, if the pulse be not excessively weak, and the heart's action almost fluttering, recourse must be had to venesection. Slow and deep breathing, with a tendency to stertor, add greatly to the necessity of immediate bleeding. The beneficial action of the withdrawal of blood is shown by the pulse becoming fuller, stronger, and better in tone. The
opening into the jugular is to be a large one, in order that the blood may flow freely to relieve the congestion, to check, if possible, a further extravasation of blood or effusion of serum, and to divert its active flow into the head; but it must not be carried out so as to debilitate the heart's action. When the pulse becomes fuller and stronger, the bleeding is to be stopped; from three to five quarts will generally be sufficient.

The bleeding is for the purpose of removing pressure from the brain, and although the pulse may indicate stimulants rather than depletion, it will be found that as the blood flows the tone of the pulse will improve, for the weakness of the pulsation, the want of impulse, and debility of the heart's action, are results of brain pressure. If, however, the surface of the body be cold, the animal tympanitic, the heart's action fluttering, and the pulse almost undetectable, bleeding is calculated to do more harm than good, as the heart's action would now be further impaired, and the amount of arterial blood sent to the brain diminished; for it must be remembered that the cerebral congestion is now less due to an over-abundant supply of arterial blood than to pressure upon it by venous or capillary engorgement; that, in fact, the brain—engorged as it may appear—is in an anaemic condition in regard to its arterial supply; and when this is the case, paralysis of the heart is to be prevented, if possible, by the use of stimulants. It is the practice of many veterinarians, and of its success I can speak with confidence, to bleed to relieve congestion, and administer a stimulant to increase the heart's action; to enable the heart, in fact, to send arterial blood into the brain by overcoming the resistance of the congestive venous pressure.

If the cow is already down when first seen by the practitioner, his first care must be to see that it is made to lie as near the natural position—on the sternum—as possible, and this he will do by having it packed up at the side by bundles of straw, or, what is better, sacks filled with straw, firmly wedged under the quarter and shoulder, the head at the same time being properly propped by the same means; and care being at all times taken that the cow is prevented from injuring its head by striking it against hard bodies. When this is done, veneesection may be had recourse to.

In all cases, whether the pulse be small or full, a strong
cathartic should be administered, consisting of sulphate of magnesia, with croton, ginger, or other aromatic, care being taken that the animal is not choked, as the act of deglutition is often performed with difficulty. I always try if the animal can swallow a little water from a bottle before administering any medicine. If the patient shows any difficulty in doing this, the medicine is to be given with the stomach pump. I am of opinion that the cathartic should not be repeated, having seen the repeated administration of even simple fluids cause tympanitis and death. Cold water is to be applied to the head; the spine along its whole course stimulated with strong ammonia liniment, and the animal warmly, but not heavily, clothed. Every two or three hours it is to be turned and packed on the other side of the body; the mammary gland stripped and hand rubbed, and should there be signs of exhaustion or failure of the heart's action, a stimulant is to be administered; the best way of doing this is to give ammonia carbonate in a ball, which, after being oiled, is to be pushed by the hand as far as possible into the pharynx, when it will slowly gravitate into the rumen. If the tympanitis is not relieved by the ammonia, the rumen is to be punctured by the trocar, and the cannula left in. Enemas of warm water are to be repeatedly injected into the rectum, the urine withdrawn, either by the finger introduced into the bladder, by the female catheter, or by introducing the nozzle of the ordinary injection syringe.

Some practitioners recommend nux vomica to be given every few hours. There is no objection to a single dose of this being given along with the cathartic, but its repeated administration can only do harm; the paralysis depends upon engorgement, and spinal or nerve stimulants in the acute stages of the disease are contra-indicated.

The pouring or pumping of large quantities of fluids, consisting of sundry quarts or even gallons of water, with treacle, ginger, &c., for the supposed purpose of causing purgation, is also to be condemned; the fluid absorbed, whilst the excretory organs are not performing their functions, only adds to the general p lethoric condition.

To prove the injurious consequences of this practice, as well as that arising from feeding the animal upon thin sloppy food
after parturition in order to prevent this disease, I will quote a parallel from human pathology.

Niemeyer says, under the head *Hypertrophy of the Heart*—

"Such patients must be aware of immoderate eating and drinking, in order to avoid the plethora which, although but transient, always follows the free use of food and drink. How often does the long-threatening apoplexy set in in the midst of the plethora which has developed after a long and hearty meal? In this connection, I may mention an act of folly which I have often seen practised by tavern-keepers and itinerant wine-dealers. The latter suppose that by a free use of water they can counteract the pernicious influences to which they expose themselves, although it is evident that the plethora arising after a full meal would only be increased by an immoderate addition of fluid."

When consciousness has returned, and the animal seems in a fair way of recovery, no medicines should be administered; but if at any time there are signs of exhaustion or sickness, small doses of spirits of nitrous ether and water may be administered, provided the animal is conscious and can swallow freely.

In some instances the appetite is inordinate immediately after consciousness has returned; the animal will greedily devour any hay or straw that may be about it. This must be prevented by muzzling it at once, or a fatal attack of indigestion with tympanitis will be the invariable result. Small quantities of water or thin gruel may, however, be allowed, and all food given very sparingly until rumination has been fully re-established.

There are two sequelae which often annoy the practitioner when he has congratulated himself upon a successful case, namely, congestion of the lungs, and paralysis of one or both hind extremities.

Congestion of the lungs appears about the third or fourth day. The cow, in the meantime, having perhaps been on its feet repeatedly, giving milk freely, &c., suddenly begins to breathe heavily and quickly, the pulse becomes oppressed and rapid, and the animal quickly sinks. In some instances the lung complication is due to inflammation of the bronchial tubes, excited by the incautious administration of fluids during
the comatose stage; such fluids having passed into the trachea and lungs, and causing inflammation, which is manifested whilst the animal is otherwise recovering. An abundant secretion of mucus, with cough and mucous rales, indicate this, but undoubtedly congestion of the pulmonary system arises frequently, and independently of the irritation of foreign agents in the bronchial tubes, and is due to the mal-condition of the blood, resulting from retention within it of effete materials, and from debility of the heart's action. It is best treated with stimulants and hot fomentations to the sides. It is, however, very fatal.

The other sequel, namely, paralysis of the hind extremities, very often baffles all attempts to overcome it, and is due to inflammation and red softening of the cord in the lumbar region. If the cow is not up about the second day after consciousness has returned and after it has commenced to improve, paralysis may be expected to be present. It is very true that some cows, out of sheer obstinacy, will refuse to rise upon their feet, although the practitioner knows well enough they can do so if they like.

Many a cow will do this until it sees some hateful object, such as a dog—and it is a common practice to introduce a dog into the byre—when her ladyship very soon takes to her feet. This is a harmless, and sometimes a very effectual practice. At other times, believing that paralysis is present, and is to be overcome by severe counter irritation, the veterinary surgeon has applied the actual cauterity to the lumbar region. The touch of the hot iron has been enough; with a loud bellow and a dash, it has jumped to its feet, and, if not fastened, has made good use of its hitherto supposed paralyzed legs.

When paralysis is actually present, and if the animal is in good condition, it is better to make it into beef, as too often the use of the limbs is never restored, more especially if it is a heavy, fat cow.

The treatment consists in the application of the actual cauterity to the loins; blisters, purgatives, succeeded by iodide of potassium and diuretics, to excite the absorption of any exudation which may press upon the cord, and finally nux vomica and sulphate of iron. In some instances one leg only is paralyzed, and the animal is able to rise with a little assistance. Many
cows, however, resist any attempts to help them, and will struggle up if left alone; drag the paralyzed limb, "knuckle over" at the fetlock for a time, and finally recover.

I may state, in conclusion, that parturient apoplexy is a recurring disease, and that it is not safe to allow a cow to calve after it has once been down; and if the owner consults his own interests, he will milk it as long as possible, and then prepare it for the butcher.
CHAPTER XLIII.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(F.) ADVENTITIOUS SUBSTANCES IN THE BRAIN AND CRANIAL CAVITY—CAUSING, GENERALLY, SYMPTOMS OF CONDITIONS VARIOUSLY TERMED SLEEPY STAGGERS, IMMOBILITY, COMA, &c. &c.

TUMOURS.

Tumours are generally found in the choroid plexus. They are very commonly met with in both plexuses, sometimes larger in one than in the other; very often quite symmetrical in size and position. They grow slowly, and scarcely ever affect the health of the animal, or give any indication of their presence, until they have attained a size varying from a pigeon's to a hen's egg. They consist of a caseous material, mixed with a calcareous matter; they are in fact composed of an exudation which has undergone the caseous and calcareous degeneration. These calcareous particles are called brain sand—psammoma—and are never found post mortem presenting signs of recent origin.

I have found these psammomatous tumours in horses of various ages, but most commonly in old horses.

When they have attained the size above mentioned, they, in some instances, give rise to severe convulsive fits, a staggering gait and inability to perform work, whilst in others their presence is not indicated by any symptoms prior to a final stroke, simulating apoplexy, to which the animal rapidly succumbs. In those instances, when they occasion disturbance prior to the fatal attack, the symptoms vary somewhat in character; in one animal there will be unconsciousness, with elevation of the head and fore part of the body; in another—and this is rather a
frequent symptom—there will be a tendency to keep the head in a depressed position. In one case this depression of the head was very marked, but this did not happen until the animal—a mare—was worked or exercised; when kept quiet it appeared in the best of health in every way, but if exercised, no matter how slowly, depression of the head—the nose being almost brought to the ground—would always occur. This animal had, shortly before presenting these signs, recovered from an attack of farcy, affecting the cervical and facial absorbents. When I saw it I expressed an opinion that there was a tumour in or upon the brain, due to or connected with the previous farcy. I may mention that the cervical lymphatics were still enlarged, but showed no signs of recent inflammation. The probable age of these ventricular tumours is sometimes a question of importance as connected with the soundness of a horse prior to purchase; and it is well to bear this in mind, as an animal may die from an attack of cephalic disease, and upon a post mortem examination being made, these tumours may be found in the lateral ventricles. The clinical history of these points out that they are of slow growth; that they do not cause any disturbance until they have attained a certain size; they do not, at least in all the instances that I have met with or heard of, give rise to disturbance, increasing in severity as they slowly grow; but all at once, when they have attained the size of a small egg, signs of a severe cerebral disease occur, which ultimately proves fatal. Examination of the brain and tumours reveals—1st. The lateral ventricles nearly or completely filled by the growths; 2d. The tumours themselves firmly encapsulated in the folds of the choroid plexus; 3d. Absence of congestion, injection of the vessels, and other signs of recent inflammation; and 4th. A caseous and calcareous change of the interior of the tumours.

**Thickening of the dura mater.**—Thickening and induration of the dura mater consequent upon a slow chronic inflammation is of very rare occurrence. I have one case on record, however, in which the dura mater attained a thickness varying from one inch at the base to several inches at the anterior part of the cranium, causing absorption of the descending (orbital) plates of the frontal bones and wings of the ethmoid, and filling the frontal sinuses. The horse in which this was discovered had presented signs of brain disease, coma, immobility, partial
paralysis, amaurosis, and paralysis of the muscles of mastication, for a considerable period before its death. The post mortem examination revealed that the bones above mentioned had been absorbed, the frontal sinuses filled with a white mass resembling brain, but which proved to be thickening of the dura mater; the brain compressed, very solid in consistence; the lateral ventricles almost obliterated by approximation of their sides and roof, and the brain generally anaemic. There was no previous history to this case. It is very probable, however, that this condition was a result of an injury, such as a blow upon the head, causing perhaps partial detachment of the dura mater without fracture of the bones, and consequent chronic inflammation.

In another case there was enlargement of the lacrimal gland causing absorption of the bones of the orbit, and death by pressure on the brain. The cranial bones as well as the brain are now in my possession, and were obtained from an old horse, which had presented no signs of disease, except a slight difficulty in masticating its food for a few days prior to death, and at first was supposed to be another specimen of induration of the dura mater; but further examination proved it to be due to enlargement of the lacrimal gland. In addition to penetrating the cranium, the tumour partly filled the frontal sinus on the same side, causing partial absorption of the orbital process of the frontal bone; but the most remarkable circumstance in connection with the progress of the case was the fact that at no time was there any bulging or undue prominence of the eye; a condition that one would have supposed would have been a more likely one to occur than absorption of the osseous walls of the orbit.

The tumour measured several inches, was lobulated in character, and microscopically was found to consist of numerous cells imbedded in a few very delicate fibres. The tumour presented no signs of retrograde change, and partook of the character of lymphadenoma in many particular.

TUBERCULAR DEPOSITS IN THE MENINGES OF THE BRAIN.

Tubercular meningitis—a disease not rarely met with in the human being, more especially in the young—is a very rare affection in the lower animals. I have seen but two cases of it—in calves about three months.
The symptoms were those of nervous derangement, partial paralysis, squinting, contraction of the pupils, fits of convulsions, succeeded by coma, loss of motor power, amaurosis, and death. In one case there was indigestion, purging, the faeces being white, and consisting of the milk the animal was fed upon, loss of flesh, hardness of the belly, and emaciation. In the other case the digestion was good, and the body fairly nourished.

In addition to small tubercular deposits, scattered here and there on the membranes—caseous and calcareous, acrofulous tumours were found in the peritoneum, in the mesenteric glands, and in the pleura. Very probably the condition termed hydrocephalus, or drop of the brain, is due to the development of tubercle during fetal life.

**EXOSTOSES**

Are met with in horned cattle. These consist of enamel-like growths of a globular nature, sometimes convoluted, and attached by a pedicle. They dip, along with the dura mater, into the convolutions of the brain, and seem to be due to ossification of the dura mater.

Mr. Gamgee reports a tumour having the appearances of an ossified brain, which is in the Milan Museum; and states that these growths sometimes attain the size of an ox's brain, without inducing any apparent disorder until the animal's sudden death.

I have seen in the horse tumours having a resemblance to dentine invading the temporal bones, both externally and internally; and these, like the bony tumours of cattle, have induced no marked symptoms during life.

**HYPERTROPHY AND ATROPHY OF THE BRAIN**

Are conditions unknown in the lower animals. In my work on the *Principles and Practice of Veterinary Surgery*, page 182, a case is described of apparent hypertrophy of the brain; but in reality the apparent enlargement was due to development of fibrous tissue in the brain, which of itself was not enlarged. In the case of thickening of the dura mater mentioned at page 504, the brain was atrophied by compression owing to the thickening of the dura mater.
MELANOSIS OF THE BRAIN AND MENINGES.

Small, black, melanotic nodules, varying in size from a pea to that of a bean, were found in the brain and on its meninges in an aged grey stallion which had suffered for a number of years from "stringhalt." Not only were they found in the cranial cavity, but along the course of the spinal cord, being particularly numerous in the lumbar region.

ENLARGEMENT OF THE PINEAL BODY.

This body is sometimes found enlarged, and sometimes converted into a cyst, containing a whitish viscid fluid. The pituitary body may also be found in a similar condition. These appearances are met with in old subjects on the dissecting table. There are no appearances which indicate their presence during life.

Parasites in the Brain.—(See Parasitic Diseases.)

SOFTENING OF THE BRAIN.

I have already stated that softening of the brain occurs as a sequel of epizootic cellulitis, and that it is due to plugging of the cerebral arterial branches.

All the conditions mentioned in this chapter may give rise to what is termed immobilité by French veterinarians—coma somnolentum by writers on human medicine, and sleepy staggers by old writers on farriery; a manifestation or expression of brain disease characterised by general dulness, a tendency to fall asleep when allowed to stand quiet for a while, tripping or falling, staggering gait, slow pulse, and deep respiration. An animal suffering from this will often fall asleep with its mouth full of food. It is, however, easily aroused, and if this be done suddenly, will manifest fright, trembling, and a disposition to delirium.

For the relief of these symptoms an occasional purgative ought to be administered, the animal carefully fed, and worked gently, so long as it remains serviceable, after which it should be humanely destroyed, as it is useless to endeavour to cure what is organically changed. Hence all irritating materials in the form of blisters, setons, &c., should be avoided.
CHAPTER XLIV.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(G.) DISEASES OF THE SPINAL CORD AND ITS MEMBRANES.

Inflammation of the spinal cord and its meninges is described as two separate diseases by human pathologists, and is termed myelitis, when attacking the substance of the cord; rachidian arachnitis and spinal meningitis, when involving the membranes only. I think that in the lower animals the distinction is unnecessary. I shall therefore describe the disease under the generic term.

SPINITIS.

Idiopathic inflammation of the spinal cord and its membranes presents itself in the horse in two forms, namely, acute and chronic.

The symptoms of acute idiopathic spinitis are not always alike. In some instances the paralysis, which results in every case, may be manifested suddenly, and with little or no previous premonitory signs of ill health, the animal losing all power of movement over all parts posterior to the seat of inflammation; whilst in others, symptoms of cramp or spasm, great restlessness, and a high degree of fever may for some time precede the paralysis.

The following case will illustrate this form of attack:—A grey cart gelding, six years old, in previous good condition, and at regular work, was observed to perspire profusely, to breathe quickly, and to express signs of great restlessness; the hind feet were alternately lifted from the ground with great
violence, the great muscles of the thighs were violently cramp’d, and such was the degree of pain that it became almost unmanageable. It was led home and placed in a loose box, where it lay or almost fell down. For a while it seemed relieved, but after a time commenced to struggle violently, and at last managed to regain the standing posture. The cramp of the limbs returned; after an interval it again lay down, and when first seen by me it was struggling violently, breathing heavily, and groaning with pain; the pulse about ninety, and full; mucous membranes injected, and the body bedewed with sweat. It again struggled to its feet, passed some rather high-coloured urine; remained quiescent for a short period, and then the great struggle again commenced. It was placed in slings, into which it threw its weight, and gave a sigh of relief; after an interval of about fifteen minutes it commenced to struggle violently, its hind legs were dreadfully cramp’d, and we were obliged to lower it down on to its bedding, when it again seemed to receive relief. It was bled and a purgative with belladonna administered, the loins and back were fomented with hot water, mustard applied, and afterwards covered with a sheep-skin. In a while, however, it commenced to struggle afresh, and we were compelled to raise it by pulleys and slings. For two days and two nights it thus remained, now and then free from pain, then in dreadful agony; it seemed that all movement hurt it dreadfully, every jerk and start causing it to groan and to jump as it were in agony. At first the muscular convulsions were confined to the posterior extremities, but the fore limbs became after a time affected. The poor horse seemed to dread moving its limbs, but a sudden start would ensue, and all its limbs would move convulsively and with great force. We were compelled alternately to sling and let it down, for in no posture could it obtain ease for more than a few minutes at a time. On the third morning the spasms left it, the bowels responded to the purgative, the respirations became slower, but the pulse was feeble, thready, and greatly accelerated, beating about 130 per minute. It could now stand for some hours, but if made to move it did so with great difficulty, dragged its hind limbs, staggered, and was inclined to knuckle at the fetlocks; the off fore limb was also partially paralyzed, and was moved with difficulty. When last seen by me it was standing with its head over
the box door, and looking pretty cheerful, had drank some gruel and eaten a little hay, and I was in hopes it might rally; but shortly afterwards it fell completely paralyzed, lost both motor power and sensitiveness; there was no struggling now, it lay passively on its side, looked quite conscious, and died without a struggle. A post mortem examination revealed the spinal cord and meninges highly congested, and the subarachnoid space filled with serosity. The dorsal, lumbar, gluteal, and the muscles of the thighs, as well as the serrati magni, levatores humeri, triceps extensor brachii, and the other muscles which had been violently cramped during life, presented a dark, congested appearance.

The spinal congestion was most marked in the dorso-lumbar region, and both roots of the spinal nerves, and the nerves themselves for some distance, presented the same appearance. The arachnoid, pia mater, and dura mater were intensely red; the substance of the cord looked reddish, and on cutting through it black blood exuded abundantly from its centre.

The other form of spinitis is that manifested by sudden loss of power, without previous irregular muscular action, and may be appropriately termed inflammatory paralysis; for, in addition to the paralysis, there is fever, constipation of the bowels, diminished secretion of urine, and other signs of constitutional disturbance. This form is apt to be confounded with fracture of the vertebrae, more especially of the lumbar vertebrae, in which generally the paralysis is complete immediately after an accident. Whereas, when one of the dorsal vertebrae is fractured, displacement may not immediately occur, displacement and paralysis occurring perhaps in a few hours after the accident.

The history of the case will have to be taken into consideration in arriving at a diagnosis. Broken back generally succeeds a traceable accident, acute spinitis without any appreciable cause.

The first form of spinal inflammation is apt to be confounded with azoturia. The dark colour of the urine which characterises that disease is absent in spinal inflammation, and the spasm, which in azoturia is mostly confined to the gluteals, affects various muscles, and is of a more clonic or alternating kind.
CHRONIC SPINITIS.

This again presents itself in two forms, namely, that associated with tonic spasm of the voluntary muscles, and that associated with paralysis of particular muscles.

Chronic spinitis associated with exalted muscular contractility is in some districts termed the "cords," from the fact that the superficial muscles have a prominent or corded appearance.

The symptoms are at first obscure. There is some degree of stiffness about the spine, the animal turns with difficulty, and often groans when made to do so suddenly. Some particular muscle is now seen to stand out from its fellows, and present a permanent rigidity and hardness. Very often the muscles of the shoulders or the levatores humeri and cervical muscles are first affected; but gradually the whole body becomes more or less stiff, the limbs are flexed with difficulty, the nose elevated, and the animal seems as if affected with chronic tetanus; the facial muscles, however, remain normal, and the animal continues to feed well. After the lapse of some weeks, the hind limbs become feeble; there is knuckling over at the fetlocks, crossing of the feet, staggering gait; the animal seldom lies down, and rises with great difficulty, and eventually becomes paralyzed, and has to be destroyed.

In the other form the first symptoms are, staggering gait, weakness of the hind legs, crossing of the feet, and a gradually increasing loss of motor power, until finally the animal becomes powerless, unable to rise from the recumbent posture, and has to be destroyed. In none of these cases—acute or chronic—do we find that the sphincters lose their power of contractility, nor is common sensibility lost. Indeed, in the acute form, I have often thought there was hyperaesthesia, and that the animal dreaded the touch of its attendant. These conditions indicate that the meninges are the principal seat of the inflammation.

The post mortem.—The spinal cord is red, injected, and softened (red softening), the meninges thickened, the arachnoid covered with an exudate, which in some places joins its opposed surfaces, or is filled by a semi-purulent or reddish serosity. In one case, which died during very cold weather, the fluid, being frozen, after death presented a very beautiful appearance.

Idiopathic spinitis differs from that arising from external
injuries or disease of the bones, in which the dura mater is
inflamed on its adherent surface; the areolar tissue uniting it
to the spinal canal is loaded with venous blood, or sometimes
broken down, and the dura matter separated from its attach-
ments.

The causes of idiopathic spinal inflammation are very obscure.
Very probably it is often due to rheumatic inflammation localized
in the membranes primarily, the cord itself becoming secondarily
affected. In Principles and Practice of Veterinary Surgery, page
248, I have pointed out that hereditary tendency is a cause of
spinal affections.

TREATMENT.

The acute forms are to be treated antiphlogistically; blood
may be withdrawn and purgatives administered; depletives must
not, however, be pushed too far, as acute spinal diseases have a
lowering or debilitating effect upon the system. The purgative
may be combined with belladonna, which will to some extent
relieve pain and spasm, as well as overcome the congestion of
the spinal vessels. Hot fomentations to the back and loins are
indicated in the earlier stages, and blisters, or even setons, should
there be but a partial recovery. It must be remembered that a
continuance of the symptoms, after the acute stage has passed
off, depends upon some degree of effusion or exudation, and that
means must be taken to promote absorption. On this account
iodide of potassium with diuretics is indicated. Ergot of rye
(Scalle cornutum) in combination with the iodide of potassium
is well spoken of by physicians, and may be tried in the lower
animals.

In all cases great care must be taken that the urinary bladder
be regularly emptied; and if micturition is not naturally and
easily performed, the catheter must be used at least thrice a day.
If the animal is recumbent, this should never be neglected. The
attendants must also be directed to turn the patient every now
and then, see that enemas are regularly administered, and that
the bed is kept clean and dry.
CHAPTER XLV.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(H) PARALYSIS.

Palsy or paralysis may be seen in various forms rather as a symptom of a lesion than as a disease itself, the term palsy or paralysis being commonly restricted to that form where motion is lost, while the term anaesthesia implies a palsy of the nerves of sensation.

In order to understand the various lesions which may cause paralytic symptoms, it is advisable that a glance at the physiology of the spinal cord should now be undertaken.

1. The spinal nerves have two roots; and Sir Charles Bell proved that the anterior (inferior in the lower animals) conduct the power of motion, whilst the posterior (superior) are devoted to sensation only. At one time it was thought that if the corresponding columns of the cord were cut or injured, loss of sensation only would result when the superior columns were cut, and loss of motion if the inferior were cut across; but such is not actually the case, for it has been demonstrated that if the posterior columns are cut across, the result is not numbness and insensibility, but hyperaesthesia and loss of co-ordinating power in the parts posterior to the section, with some local pain, due not to any sensitiveness in the columns themselves, but to the cut having traversed through the posterior roots of the nerves. The same results are obtained if the restiform bodies and small superior pyramids are divided, and as these parts are connected with the cerebellum, and the superior columns of the cord, the deduction is, that the channel which
conducts the action of the cerebellum upon the body is composed of the restiform bodies and small posterior pyramids in the anterior part, and of the superior columns of the cord in the posterior part of its course.

Section of the inferior columns, if made immediately behind the medulla oblongata, is not followed by any very obvious loss of paralysis or loss of sensation, unless the cut be extended to the lateral column, when loss of motion is the result, as if the columns were divided behind this point. It is therefore apparent that in the anterior part of their course the inferior columns have not an intimate connection with the corresponding roots of the spinal nerves. Posterior to this, however, they have a close connection with the inferior roots of the spinal nerves and with voluntary motion. They have also some connection with sensibility, as a certain degree of numbness is produced by injuries which give rise to loss of motion.

**Inferior pyramids.**—Section of one of these pyramids in any part of its course is followed by immediate loss of voluntary movements in the muscles below the cut on the opposite side of the body; but sensation is not affected in any appreciable manner.

**Lateral columns.**—In the cervical region, for a short distance behind the point at which the inferior pyramids of the medulla oblongata decussate, the lateral columns of the spinal cord are directly concerned in conveying the stimulus of the will to the muscles on the same side of the body, for when they are cut across paralysis of the muscles of the same side occurs.

In the lower part of the neck, and regions posterior to this, the same results are not seen; for when they are divided in these regions, some trifling paralysis ensues, with some degree of anaesthesia and loss of co-ordination.

**Olivary bodies.**—When one of these is divided, a persistent spasm of many muscles of the same side is the result.

**Grey substance of the cord.**—Dr. Brown Sequard says that the grey substance of the cord is an important conductor of sensory and motor impressions. Paralysis, without loss of sensation on the same side of the body, are the results of cutting across one lateral half of the grey substance of the cord. Anaesthesia on both sides of the body, paralysis of neither side, are the strange results of making a longitudinal section midway between the two lateral halves.
The superior half of the white matter may be divided at one point, and the inferior half at another a little anteriorly, so that all the white fibres shall be divided transversely by the one cut or the other, without any material continuity of the cord or damage to the grey matter; and when this has been done, irritation of the sensory nerves connected with the parts below the section excites the sensation of pain as strongly as ever. Hence it follows that the impulses which excite pain reach the brain through the grey matter, and so long as a small portion of the grey matter remains intact, these sensations are transmitted.

If one-half of the cord be cut through transversely down to its very middle, so as to interrupt all continuity of both white and grey matter, irritation of the skin of the same side will give rise to as much pain as if the cord were not cut, but all voluntary power will be lost in the muscles of that side below the section. It thus follows that the channels which convey sensory impulses must cross over from the side of the cord which they enter to the opposite side, and that the motor influences sent down from the brain must travel along that side of the cord by which they pass out.

There is increased temperature and sensibility on the side in which sensation is preserved, and diminished temperature on the side in which sensation is lost, especially if the section is made near the medulla oblongata.

It would seem that the injury acts upon the vasa-motor nerves contained in the cord, as well as upon the motor and sensory nerves (it may be here stated that the vasa-motor fibres do not arise from the sympathetic ganglia, but simply pass through them on their way from the spinal cord to the upper dorsal region), causing paralysis of the vasa-motor nerves on the side in which there is increased temperature and sensibility, and irritation of the vasa-motor nerves on the side in which there is diminished temperature and anaesthesia; for the experiments of Dr. Brown Sequard, Claude Bernard, and others have proved that when the cervical sympathetic is paralyzed by dividing it, a state of congestion, of which the most conspicuous signs are a blood-shot state of the conjunctiva and lining membrane of the ear and nostril, with a contracted pupil, and increased temperature, is at once set up on the same side of the head, and also
that when the end of the divided nerve is irritated, the immediate result is dilatation of the pupil, with an immediate cooling and blanching of the parts which were blood-shot and warm.

Injuries to the cervical portions of the spinal cord are followed by a remarkable elevation of the animal heat. In one case of injury in a man where there was a forcible separation of the fifth and sixth cervical vertebrae, with extravasation of blood into the theca vertebralis and laceration of the lower part of the spinal cord, although the breathing was performed by the diaphragm only and very imperfectly, the pulse weak and countenance livid, the thermometer indicated 111° F.—(HUXLEY, BROWN SEQUARD, CLAUDE BERNARD, DR. RATCLIFFE.)

Such, then, are a few facts which serve as indications of the seat of spinal lesions.

In all cases of disease or injury to the cord the paralysis occurs in the parts to which all the nerves originating posteriorly to the seat of the lesion are distributed. If the injury or disease be in the sacrum the tail alone is paralyzed; if in the lumbar region the hind legs are paralyzed; and if the disease or injury be very great the sphincters of the anus and bladder may be paralyzed. If the injury be higher up, in addition to loss of voluntary power in the hind limbs, the abdominal muscles will be paralyzed, and the expiratory movements performed with difficulty.

If the disease be low down in the cervical region, the muscles of the fore limbs, as well as those of respiration, will be paralyzed, and both expiratory and inspiratory movements will be difficult; and if the injury be above the middle of the neck, or anterior to the fourth pair of spinal nerves, death will at once result from paralysis of the diaphragm, the serrati magni, scaleni, intercostales, and other muscles of inspiration.

Paralysis as seen in the lower animals may be divided into—1st. Paraplegia; 2d. Hemiplegia; and 3d. Paralysis originating in injury to a motor nerve, as paralysis of the lipes, described at page 496 of Principles and Practice of Veterinary Surgery.

PARAPLEGIA,

Or Paralysis affecting a portion of the body transversely.—Of this kind three forms are met with in veterinary practice, namely
PARALYSIS.

1st. Centric, or that arising from disease of the spinal cord or its membranes. Symptoms simulating paralysis may occur from occlusion of the iliac arteries.—(See Veterinary Surgery.) 2d. Eccentric or reflex paraplegia; and 3d. Paralysis due to blood poisoning.

Of centric paraplegia but little need be said; it is symptomatic of conditions of the spinal cord and its membranes already described, or it may result from injuries to the cord arising from violence, fractures, &c.

REFLEX PARAPLEGIA.

In horses, cattle, and dogs, spinal paralysis is met with in which no disease of the cord or its meninges can be detected post mortem in those which die, and which, in many cases, is quite ephemeral, passing away when its cause is removed.

The causes of reflex paralysis as seen in the horse are those originating in indigestion, constipation of the bowels, and, in the mare, uterine irritation.

Paralysis arising from indigestion is occasionally witnessed during attacks of colic, the loss of power coming on rather slowly; the animal is at first seen to show weakness of one hind limb, with knuckling over at the fetlock, and difficulty of moving it, than the opposite limb may become affected; and if the loss of motor power be great, the animal falls upon its haunches, and is unable to rise. If it be a docile animal and will lie quietly, the paralysis may disappear in a few hours, or leave only such traces as weakness of the limbs and staggering gait, which may take some days to pass away.

In mares, during the period of oestrus, I have repeatedly seen cases of paraplegia, generally preceded by some irregular muscular action; persistent tonic spasm of the muscles of the hind quarters, continual kicking with the hind feet, with great injection of the vulva, succeeded by loss of motor power, and even death.—(See Hysteria.) In dogs, paralysis, even affecting all parts of the body except the head, is not an infrequent result of the irritation of teething, indulgence in rich food, and want of exercise. In horned cattle paraplegia is not an infrequent symptom of indigestion, arising from impaction of the rumen, and from uterine irritation, post-parturient. I have already mem-
tioned a case of general paralysis succeeded by congestion of the brain and death in a goat, arising from grief at the loss of her kids; this may justly be called emotional paralysis.

The differences existing between reflex paralysis and that from disease of the cord is found in the circumstance that recovery is not at all an infrequent result, and that when death occurs either from the gravity of the primary disease, restlessness of the animal, or other circumstances, no spinal post mortem lesions are discoverable.

It is supposed by Dr. Brown Sequared that reflex paraplegia is not due to spinal congestion, but to a condition diametrically opposed. He believes that a state of irritation, commencing eccentrically, is propagated along the vasa-motor nerves, of which the result is, primarily, contraction of blood-vessels in, and, secondarily, exclusion of the due amount of blood from, one or more of the three parts following—the spinal cord, the nerves proceeding to or coming from the cord, the muscles, and that the proper activity of the nervous tissue is starved into paralysis from want of blood. This view is founded by Dr. Brown Sequared upon the fact that a state of irritation in the vasa-motor nerves may proceed from a distant point, and produce contraction of the vessels, and upon the fact that traces of organic disease are wanting after death in many cases of reflex paraplegia.

The following are among the causes of reflex paraplegia in the human being:—Irritation of the urethra; inflammation of the bladder; diseases of the prostate and kidneys; enteritis; the presence of worms in the intestines; dysentery; diphtheria; diseases of the lungs and pleura; the irritation of teething; irritation of the cutaneous nerves generally following cold and wet; and diseases of the knee joint.

Four different conditions of the muscles are observed in paralysis in the human being, some of which are also observable in the lower animals:—(1.) A condition little different from that of health, but less firm, less excitable by the galvanic stimulus, when the paralyzing lesion is not of an irritative kind. (2.) Complete relaxation of the muscles, characterised by imperfect nourishment and rapid wasting—so rapid that in a few days the size of a limb experiences a marked diminution. Such muscles scarcely, if at all, respond to the galvanic stimulus. (3.) Contraction of the muscles, with rigidity and wasting (the
PARALYSIS.

flexors being always more rigid than the extensors), a condition which is due to chronic shortening of the muscles themselves, and generally associated with muscular atrophy. (4.) Nutrition not impaired, constant firmness and rigidity, incomplete paralysis, increased susceptibility to galvanic stimulus.

In the treatment of reflex paraplegia the removal of the eccentric cause must always be the primary object of the practitioner. In the horse, if there be colicky pains and constipation, opium and purgatives, succeeded by belladonna, and an alkaline carbonate; the soda bicarbonate in all cases arising from indigestion. If congestion of the cord is suspected, belladonna or the ergot of rye are indicated. Generally, however, it is found that in the lower animals reflex paralysis is ephemeral, and passes away when its cause is removed.

In the cow the stomach and bowels are to be unloaded by strong cathartics. Sulphate of magnesia, with croton, if there be no actual inflammation of the stomachs; oleaginous purgatives, with opium, belladonna, or hyoscyamus, if inflammation is suspected.

In the dog reflex paralysis is often accompanied by great irritation of the stomach, vomition, and intestinal pains. Castor oil and hydrocyanic acid are the most useful agents in affording relief. If the stomach be too irritable to retain the oil, the hydrocyanic acid is to be given alone, or in combination with carbonate of soda, until undue irritability is allayed, then the aperient is to be administered. Iodide of potassium and the soda carbonate agree better, and are more useful in the dog than all other remedies after the aperient has operated. If the disease be due to decayed teeth or the irritation of teething, relief must be afforded by extraction of the teeth or lancing of the gums. In all animals cathartics, enemas, fomentations to the loins, hot baths for the dog, and emptying of the bladder, where possible, are not to be lost sight of. If paralysis continue for a time, nux vomica and ferruginous tonics may be prescribed advantageously, and the loins may be blistered, and galvanism applied.

HEMIPLEGIA.

Hemiplegia is that form of paralysis in which one lateral half of the body is affected. It is a very rare form of disease in the lower animals. I have, however, seen it in the horse,
and Mr. Mahony, V.S., Templemore, in a letter to me, December 1878, describes a well-marked case. I have also seen it in the cow and in the dog.

M. Girard, Jun., has left a case on record, quoted by Mr. Percivall, which bears out many points in the physiology of the cord already referred to. He says—‘The sensibility of the left—the affected—side proved extremely acutely. The lips and also of the nose were drawn to the right side, the contrary to that to which the head and neck turned. The occlusion of the nostrils was such that the air made a blowing noise in its passage through them. The left ear was palsied, and the tongue slightly distorted. The lips and nostrils retained their sensibility, though in a diminished degree to what it was on the unaffected side. When oats were laid before the horse, it seized them with the right side of the mouth, the left remaining motionless. It experienced a great difficulty in mastication, and succeeded only in swallowing a part of its food, the remainder staying behind, lodged between the cheek and molar teeth. It could manage to pick up its oats from a plain surface, and when presented to it in a trough, it plunged its muzzle into the middle of them, opening wide its mouth. It could drink but slowly, and with difficulty, and only by thrusting its mouth deep into the water. The nostril of the affected side perceived scents. It could walk, but could hardly sustain itself after but a short exercise. If attempted to be turned to the left side, this instability became still more manifest. Pressure upon the vertebral column from the head to the tail seemed to give great pain. The respiration, although sonorous, was regular. On the fourth day, the animal, unable any longer to stand, sank down, and after several turns and ineffectual struggles to rise, rolled over and lay upon its right side. Its bowels were relieved by manual operation, its bladder with the catheter; though even after this it passed its dung, but could not posture itself to pass its urine. Its pulse, like respiration, remained undisturbed. It died on the seventh day.’

In the case of the cow the attack was of an acute kind. The animal was grazing in a field with a lot of others, and was left quite well at milking time in the morning. The field being some distance from the house, it was not seen again before evening. It was then found prostrate on the ground, lying upon its left side, and was unable to rise.
When I saw it I observed the following symptoms:—The left ear was pendulous, left eyelid drooping and closed, the eye squinted outwards. The left cheek hung down, the angle of the mouth was lower than on the opposite side, the muscles were loose and flaccid, and the lips drawn to the right side. The tongue protruded, and when put into the mouth was drawn to the right side. The neck was twisted and the head drawn to the left side. Deglutition was imperfect, but the breathing was not appreciably affected. The superficial blood-vessels of the right side were engorged with blood, and stood out prominently all over the trunk and neck. The same side was warm, whilst the opposite side was cold, and the hair was "pen-feathered."

In endeavouring to place the animal on a hurdle for the purpose of removing it to a shed, it was observed that it rolled over from the left to the right side, on which side only could it be made to lie. The bowels were constipated, and the belly tympanitic, the sphincter ani was rather relaxed, the vulva flaccid, and vagina protruding. The animal was quite conscious, but inclined to somnolency. It was bled, a purgative administered, and the back was fomented and dressed with strong ammonia liniment. On the following morning it was able to rise, but both the legs of the right side remained partially paralyzed for some weeks. The affection of the face, however, passed away during the first night, and it was able to partake of food on the following morning.

This was a case of hemiplegia due to some ephemeral disease of one side—the left—of the brain; and from the fact of the outward squinting, anaurosis, and drooping of the upper eyelid, the conclusion is, the functions of the third nerve being interfered with, that the brain disease—ephemeral as it was—involved the posterior part of the left crus cerebri. It must be remembered that, in all cases of disease affecting one side of the brain, the paralysis is on the opposite side of the neck and trunk, but on the same side of the face. It was remarkable however, in this case, that although the loss of motor power was complete, sensibility remained intact.

Paralysis from blood poisoning is witnessed in azoturia, lead poisoning, canine distemper, and grass stagers. In the human being, as well as in horses, cattle, and birds, a form of paralysis arises from the use of the vetch known as the Lathyrus sativus.
Sporadic Diseases.

—(Don, Taylor, Irving, Loudon, Sleeman). The canine distemper poison leads in many instances to softening of the cord, in which its substance is broken down and softened almost to a pulp. In recent cases the softened cord is red or yellowish-red in appearance, due to some degree of accompanying congestion. In the more chronic cases, or those which have lived for a longer period, the red appearance is absent. White softening may, however, occur quite independently of the red or inflammatory form, and is due to oedema or effusion of serum. I have repeatedly seen not only softening but apoplexy of the cord occur as a sequel to canine distemper, and in which the neurilemma of the roots of the nerves were filled by a clear fluid material, and quite devoid of true nervous matter. In softening, the grey matter of the cord is always more affected than the white. I have never seen the converse condition of the cord, namely, hypertrophy, nor induration of its substance. The treatment is the same as that for paraplegia, and in the case of a valuable animal galvanism should be tried for a prolonged period.

Louping-Ill, or Trembling.—(Chorea Paralytica Ovis.)

In the above terms is included a disease which every year entails an enormous loss amongst hill sheep, both black and white faced, particularly in Scotland. Under the auspices of the Highland and Agricultural Society of Scotland, stimulated by Mr. Eliott Lockhart of Borthwickbrae and the members of the Teviotdale Farmers' Club, who at his instigation had made investigations for some years, the author and others have been investigating the causes of this disease, and another, commonly known as braxy or sickness, referred to as a septicemic affection in another part of this work, but upon which further observations should be made hereafter. Louping-Ill.—The term "louping-ill," supposed to be derived from hluupa, an old Scandinavian term for "a staggering gait," as applied to the disease, is general in some parts of Scotland, whilst in others it is known by the term "trembling." It seems to prevail more in the Silurian hill districts of Scotland, and extends from the Hebrides to the southern extremity of Dumfrieshire, being equally prevalent in the district of Langholm as in the isle of Skye. There is this difference, however, namely, in the southern parts it rarely occurs to
any extent but during the early summer months; commencing about the middle of April, and disappearing before the end of June; whereas in Skye there are two annual outbreaks,—one in early summer, and another in autumn, commencing at the end of August, and terminating in a month or six weeks.

It is stated that it affects, but to a slight extent, cattle, horses, and pigs. I have seen well-marked cases in horned cattle, but never in horses and swine.

Symptoms.—The symptoms, as observed during my investigations in 1881 and 1882, were as follows:—

Case No. 1, May 19, 1881, Langholm District.—A three-year-old ewe was seized on the 18th, just before giving birth to a dead lamb. When seen on the 19th she was standing with head erect and brilliant eye, the upper muscles of the neck spasmodically contracted, causing the nose to be protruded as in tetanus. When made to move, she did so very stiffly and automatically, the limbs being lifted very high, and the feet planted on the ground in a peculiar jerky manner, like a horse with stringhalt. There were tonic or persistent spasms of the muscles of the loins, back, and neck, and clonic or intermittent and irregular spasms of the other muscles, particularly those of the limbs; the breathing was very jerky, quick, and irregular, being from fifty to sixty per minute when quiet; pulse 102, and temperature 105.5° F.

On being excited the ewe fell prostrate on the belly and chest, and lay with head and neck extended; on being raised, walked away trembling violently, the trembling being due to alternate contraction and relaxation of the muscles.

On examining the skin three kinds of ticks were found, but they were not very numerous.

She was killed, and on making a post mortem examination of this ewe, nothing very special was discovered; the flesh was pale, and the carcass thin, but there seemed to be no abnormality of the cord or spinal canal, beyond a slight increase of the spinal fluid. There was no jelly-like exudate on the cord, nor any congestion of the cord, or of the membranes.

No. 2.—Another ewe was recovering. She had trembled for a day, then became paralyzed, and went down and lay three days, but was then up and walking about, but in an unsteady semi-paralyzed manner.
May 24, 1881.—No. 3.—This case was seen by my son, Mr. William Owen Williams, and was in the Peebles district. Lamb about four weeks old; was in a tetanic fit; ground its teeth; rapid squinting movements of the eyes; the spasm lasted from one to two minutes; it then got up seemingly well, though dragging its hind legs; had been ill two days. Temperature 104° F.; pulse 100; respiration 40. On dissection, nothing abnormal was found beyond a jelly-like exudate in the spinal canal.

No. 4.—Ewe lamb on same farm, about three weeks old; temperature 103·8° F.; breathing very quickly; pulse too feeble to make out exactly; lying prostrate, completely paralyzed. When pricked with a pin showed increased sensibility (hyperesthesia), the reflex movements being very violent. This lamb had been ill a week, and not able to suck for the last three days. Had her killed, and found a jelly-like exudate in spinal canal. The owner of these sheep had lost four score of lambs and one score of ewes since the 1st of May, and he also lost annually from five to seven score of hoggs from braxy.

The herd stated the sheep had a tendency to eat dirt when the disease began, and that it was always worse in bleak weather.

No. 5.—June 8, Sanquhar district.—Ewe hogg; had been ill four days; was not observed to tremble, but found down, paralyzed. Was in good condition; in fact almost fat. Lay quietly on the right side; eyes open, no dilatation of the pupils, nor any squint. When suddenly approached, or otherwise disturbed, was very frightened, and struggled violently. When hind leg was lifted up and allowed to fall there was no attempt at motion, but when the fore leg was lifted in the same way there was a to-and-fro motion before reaching the ground.

When raised, and held up by hand, it could move its fore limbs pretty freely, and could stand and bear weight upon them; but the hind ones remained extended backwards, completely paralyzed, and the muscles of the hind quarter were clonically convulsed.

Sensibility was diminished in the hind limbs, but there seemed to be some degree of hyperesthesia in the fore ones, as these moved very rapidly and violently when pricked. The sensibility of the trunk seemed to be normal.

The temperature was 105·5° F., pulse 106, and respirations, when not disturbed, 30, but when excited the breathing became
very rapid, jerky, and convulsive. The *post mortem* examination revealed nothing very particular in the spinal canal, brain, nor in any other organ. The flesh was not at all pale or anaemic, as in the majority of the cases examined, and fat was abundant and very healthy looking.

During 1881 about three score of sheep and lambs were examined after death, and about one-third of these were considered to have had "looping-ill," whilst others were found to have had—(1.) "Joint ill" (suppurative arthritis); (2.) Anaemia, from pure starvation; (3.) Impaction of the stomach with wool in young lambs.

In autumn the isle of Skye was visited, but unfortunately only one case was discovered; it was, however, a well-marked one of "looping-ill," and although it presented no characteristic condition on being examined after death, it gave results which were in unison with others already observed, namely, a special organism was cultivated from the spinal fluid.

In 1882 the spring and early summer seasons were very mild, young grass was abundant, and "looping-ill" was not nearly so prevalent; but in May information was received that the disease was prevailing, and the Hawick district was visited, and cases observed and examined. The symptoms during life, and the *post mortem* appearances, were like those already referred to. In all of the cases the passage of faecal matter and of urine was normal until the paralysis became complete, when both urine and faeces were passed involuntarily. In many the appetite was moderately good even when paralysis was complete, as they would nibble the grass within their reach with some degree of avidity, and young lambs would take milk out of the bottle freely; indeed it was not until exhaustion became extreme that the appetite failed, and always up to the last consciousness remained, as evinced by moving of the ears when any sounds were made, and closure of the eyes when any object, such as the finger, was brought suddenly near them.

In one lamb, sent in from Dumfriesshire in 1882, there was a downward squint in both eyes even when in repose, but in others there was no squinting unless under excitement, when, as in the first case described, there was often a convulsive motion in both eyes.

We were informed that many sheep seemingly in good health
often make a jump and fall down, some dead, some completely paralyzed, when suddenly frightened or approached by a dog, and that there were very often no other indications of the disease.

Causes.—These are ascribed to a variety of external circumstances, such as soil, pasture, geological formation, altitude, weather, and the influence of ticks.

I. Influence of pasture, geological formation, and altitude.—Mr. Brotherston, Kelso, who has made an extensive examination of the geological formation of louping-ill districts, has come to the conclusion that it is found on very different soils, geological formations, altitudes,—close to the sea, as in Skye, and on soils and formations so far apart as the Lower Silurian, the Upper Silurian, the Old Red Sandstone, through the Carboniferous to the Basalt of the Tertiary period, and that it existed equally upon all these, provided old grasses were allowed to remain on the ground. (By old grasses is meant the growths of the last and previous years.)

Mr. Brotherston was the first to promulgate the opinion that the cause of the disease was contained in the withered grasses, as these grasses were extensively covered with a variety of micro-fungi; and that these fungi acted upon the animal body in a manner similar to that induced by ergot; that, in short, "louping-ill" was a species of ergotic intoxication or nervous excitement. This was a very reasonable conclusion, for, as before stated, the disease was not found unless portions of the ground were more or less thickly covered by grasses of last year's growth, all of which were covered with micro-fungi.

It was important to set this question at rest, and on 9th May of this year four one-year-old sheep were obtained from a district in which louping-ill was unknown, and were fed up to 15th day of June, or thirty-six days in all, upon these withered grasses, carefully collected by Mr. Brotherston in the Hawick district. After that six ewes and lambs were added to the number, and fed upon the same grasses, and remained quite free from disease. Later on, the grasses were mixed with ergots, but no effect was induced beyond a slight loss of appetite and some degree of purging.

By introducing a small portion of fungous grass into a cultivation fluid, long thread-like filaments could be grown, but these differed from what is to be hereafter mentioned, and
the above experiment almost conclusively proved that neither
the grasses nor the micro-fungi are capable of directly inducing
the disease.

Doubtless animals fed upon such poor food, particularly if
compelled to range over the hills in search of it, are rendered
feeble and incapable of resisting the influence of disease-exciting
causes, and in consequence the mortality is thus rendered
much greater than where the pastures are richer and more
nutritious.

II. The influence of the weather.—The minority of those ac-
quainted with the disease hold the opinion that a sudden change
of weather of any kind, whether from good to bad or from bad
to good, is sufficient of itself to induce the disease; whilst
others maintain that it appears only during the prevalence of
cold east winds.

These opinions are entitled to some consideration, as it is an
actual fact that the mortality is very much greater after a
sudden change, particularly—and in every instance that came
under observation during the investigation—a change from warm
to cold and inclement weather.

But neither change of weather nor exposure to its inclemency
are of themselves sufficient to induce the disease, nor does the
latter in any of its phases simulate an ailment brought about
by climatic influences; and the only conclusion that can be de-
duced from the above premises is, that inclement weather, by
its debilitating influences, predisposes to disease, and causes
many animals to succumb to what otherwise might have passed
off without very grave consequences.

One flockmaster observed that he believed the great majority
of the sheep in an infected district had the disease once in their
lives in greater or less severity during the season; that if the
food were good and the weather favourable, but few became
seriously ill, and fewer died; but if the weather became sud-
denly cold or wet, the disease was able to make a deeper
impression upon the animal body, and many then succumbed;
and further, if the disease were due to the weather, why was it
confined to certain districts, whilst in others equally cold and
exposed it was entirely unknown?

Being satisfied that the grasses, micro-fungi, ergot, geological
formations, and weather were insufficient to cause the disease,
one other probable source of it remained to be considered, namely:—

III. The influence of ticks (Ixodes).—The belief is general amongst all acquainted with louping-ill that it is closely allied to ticks; the majority of farmers, indeed, believing that the parasites, by fixing themselves in the skin and sucking the blood, cause such extensive irritation, pain, and weakness, that the animals perish from these causes, and that the convulsive spasms and paralysis are merely symptoms of irritation and debility. A very brief acquaintance with the disease, however, compelled the author to conclude that, no matter how closely allied the tick and the disease were, that irritation and loss of blood had little or no connection with the disease under consideration; for in many instances but few of the parasites were found on some of the diseased sheep, whilst many healthy ones were swarming with them, and seemingly feeling but little discomfort. It was, however, noticed that when they were very numerous on lambs, such lambs presented the disease in an aggravated form, as if the dose of the disease-inducing material had been a strong one. The belief in the influence of the tick, or its close connection with the disease, being so general, it was necessary to consider this point very carefully, with the view of determining if any relationship existed between the parasite and the disease. The result of observations on this point was confirmatory of the popular idea; for it was found—1st. That where louping-ill existed there the tick was sure to be: 2d. That where the parasites were absent there was no louping-ill: 3d. That the appearance of the parasites on the sheep in April and early summer was concomitant with the annual outbreak of the disease: 4th. That in Skye, where it is said the disease appears both in spring and autumn, it was seen by the Commission, as already stated, in autumn; and what was said about the tick being there in autumn was found to be true.

Ticks are occasionally found on land free from louping-ill. From this it must be concluded that the parasites are the conveyers or inoculators of a poison existing in the herbage or land; for by improvement of the land by ploughing and liming, by artificially feeding the sheep, and destroying or otherwise disposing of old grasses—the natural covers of the
tick, as will be shown hereafter—louping-ill has been entirely eradicated.

Fig. 19.—The Tick.

The tick is a true blood-sucking parasite, belonging to the family Ixodidae, the class Arachnidae, and order Acarinae. The mouth of the tick is provided with a serrated beak or rostrum, which enables it to pierce the skin, and retain its hold very firmly, and almost without effort, as the barbs or serrations point backwards.

The species are very numerous, but the best known are the *Ixodes ricinus*, dog-tick, the *Ixodes redivius* and *Ixodes plumbeus*, sheep and cattle tick. Those found during the investigation were recognised by Mr. Moore, British Museum, as *Ixodes ricinus*, *erinaceus*, and *marginatus*.

Ticks are said by Professor Simonds (see *Journal of Royal Agricultural Society*, vol. I., 1865) to exist in most localities, and that they specially abound in light sandy and warm districts, where brushwood, thickets, and plantations prevail. But during this investigation we found them upon every variety of soil, and at different altitudes—close to the sea level in Skye, and at a height of 2000 feet in the inland districts; in fact they will be found as high as sheep will go, provided always old grasses are abundant to afford cover, as they are thus protected from injury, and are left at comparative rest during the periods they are not obtaining blood from the animals which they attack. Prompted by hunger, they quit their hiding-places, and attack any animal which may come in their way, by plunging their beaks or sucking proboscides deeply into the skin, particularly
about the face, root of ears, lower parts of breast, between the 
thighs, in fact into those parts of the skin covered more with 
fine hair than wool.

Thus fixed, they will hang for days together sucking the blood,
until their bodies become distended to eight or ten times their 
original size, and they do not seem to quit their hold until 
they die, the eggs remaining dormant until next spring, and,
shortly after they are hatched, they most probably attack the 
sheep, and after they once bite remain firmly fixed in the skin.

It was a noticeable fact that when dead or dying sheep were 
examined, the ticks were found already dead, or in a dying con-
dition, in almost every instance of loping-ill.

Rabbits, ferrets, stoats, weasels, and more rarely hares, are 
attacked by ticks, but there are no instances recorded of these 
animals becoming infected by loping-ill. This is probably 
due to these hosts proving unsuitable habitats for the develop-
ment of the organism inducing "loping-ill," but horses are 
said to present symptoms of the disease during the loping-ill 
season.

When they first leave the ground to attack animals they are 
very small, sometimes no larger than a pin's head, and when 
very numerous make the part quite black by their numbers,
and they adhere so closely that scraping them off will tear up 
the skin.

In South America, where the parasite is called the Carpato,
it is stated that many thousand head of cattle are annually 
carried off, and frequently a scarcity is thus caused.—(Micro-
scopical Transactions, vol. 1., p. 88.)

Being satisfied that the parasites had a close connection 
with the disease (the proofs that they were co-existent upon 
certain lands, and simultaneous in their appearance, being over-
whelming), but failing to see that they caused grave disease 
and death by inducing irritation and loss of blood to any great 
extent, it was necessary to discover if any organism existed in 
sheep dead from loping-ill, and if so, to trace its source of 
origin, indeed to demonstrate if such an organism was common 
to the tick and to animals affected with loping-ill. This was 
a matter of some difficulty, as in the majority of the animals 
examined after death no really characteristic lesions could be 
detected.
In many, all parts of the body presented the appearances of health, death having been evidently due to intense nervous irritation.

In some, of course, it will be understood that there were signs of other diseases, but these in reality had no connection with the animal's death, and we are now referring to looping-ill pure and simple. In some instances there is a jelly-like formation within the spinal canal, external to the dura mater, sometimes extending in a more or less uniform layer from one end of the canal to the other, but rarely extending within the cranium. It is sometimes in patches here and there, particularly embracing the roots of the spinal nerves; generally there is a large patch in the lumbar region, then smaller ones scattered along the dorsal region; often a large patch at or about the junction of the cervical and dorsal, and very frequently a large and much redder patch immediately posterior to the foramen magnum, or entrance into the brain cavity. This jelly is seen both in lambs and in aged sheep in great perfection. It was first seen in sheep by me at Langholm on 20th May 1881, in a four-year-old ewe. I have also seen it in oxen, as well as in sheep and lambs. It is, however, not constant, even in cases that have been unwell for several days, whilst in others that have been down three or four days it is abundant. I make particular reference to this jelly, as some to whom I have shown it have asserted that it has no connection with the disease, that in fact it is a myxomatous condition of the fat surrounding the spinal cord—a condition, they say, not inconsistent with health in young animals; and that what I considered mycelia, the development of which within the body being supposed to be an impossibility, were nothing more than capillaries, and the spores blood corpuscles.

This jelly is a slimy tenacious substance, of a straw colour, and, as seen by the naked eye, lying external to the dura mater, and when examined microscopically is found to contain an organism, the Bacillus chorea oris, presenting the appearances seen in the drawings.

b b. The spore masses in filaments.  
c c. Free spores.  
d d. Micrococi.
Figures 20 and 21 have reference to the appearance seen in fresh specimens of this jelly under powers of 600 or 700 diameters, when the most characteristic structures are those to which I have applied the term mycelia, and which, as stated above, were considered to be capillaries by some savants to whom I had shown the specimens. At a in figures 20 and 21 are seen these filaments in various forms; they appear to consist of an extremely delicate limiting membrane (appearing better defined in filaments of medium size than in the larger ones) of highly refractive semi-fluid contents, and at intervals enclosed masses of spores of a still higher refractive power than the fluid in which they lie.

These spore-masses are seen at b in both figures, and at c there are a few free spores outside the filaments. Figure 21 shows the appearance I have most commonly observed; figure 20 represents a less common appearance, where they resemble berries upon short stalks.

As arguments against these mycelia or filaments being capillaries, I would point to their peculiarity of branching, the minute size of many of these branches, their behaviour on staining; and further, that the contents, instead of being shrivelled blood-corpuscles, differ very much from such bodies in their uniformity of size, smoothness of outline, and high refractive power; but, finally, the appearance of identical filaments in fluids from cultivation of the blood and spinal fluids of sheep affected with this disease sets aside completely any possibility of their being capillaries.

The fresh spinal subarachnoid fluid obtained from spines in which the jelly or mura is absent, when dried on a glass slide and stained with methylaniline, is seen to contain a considerable number of bodies, like those marked a in the drawings, and some epithelial scales, but no motile or rod-like bacteria or bacilli. When a minute drop of this clear and fresh spinal fluid is cultivated in mutton broth, even at the ordinary temperature of a room, or exposed to the sunlight in proper cultivation vessels, it gives rise to the following series of changes:—first, in about eighteen hours the fluid is seen to be more or less turbid, and if examined microscopically under a good light, and with power over 600 diameters, it will be seen to be crowded with extremely minute organisms of a cylindrical or club shape, with slightly rounded
ends, these cylindrical rods being either free or attached in chains. Some of the rows are single, most are double, and a few are triple or even quadruple.

The single free rods or bacilli are motile, and, like most bacteria, stain readily with methylaniline violet, and when so stained are easily observed.

Figure 22, drawn from a specimen procured from a cultivation in mutton broth of spinal fluid from an affected sheep, shows these rods free and in several states of attachment, as well as masses of zoogloeae with bacilli embedded in it.

A few hours later, longer chains are developed, and rod-like bacteria or bacilli having active motion are very abundant, whilst at other points distinct mycelia or spore-bearing tubes identical with those seen in the glutinous matter from the cord are visible, and masses of zoogloeae with microc cocci are seen scattered throughout the field,—figures 23 and 24, c. c.

To gain an idea of the individual character of these rods, and
also of their attachment in single or multiple chains, I refer the reader to figures 24 and 25.

A free rod or bacterium, as at $d$, figures 24 and 25, presents a somewhat cylindrical outline, slightly rounded at the extremities, with a bright line (due to refraction) running down the centre, and slightly swollen out at either end. (The appearance of this line is less given by the drawing than are the other characters.) The middle part of each rod is a little constricted, but much less so than bacterium termo; its length is about midway between that of bacterium termo and of bacillus anthracis, and the rounding of its ends is also intermediate between these two, but more nearly approaching the characters of the latter.

The character of the chains or rows of rods may be seen in figs. 22 to 25, the former under 600 diameters, showing the general appearance of single and double rows, the latter of double rows under a higher power (1200) and in various stages of detachment.

These chains present very much the appearance seen in many low forms of vegetable life, only differing in point of size. Figure 22 shows that in the double rows, so long as the rods are in lateral contact, clear division lines mark the chains transversely at intervals corresponding to the lengths of two rods, and that also less distinct cross lines are visible midway between these, marking off each bundle, as it were, into four. The single chains often present here and there an occasional filament in position alongside (see figures 24 and 25). In all of the figures are to be seen masses of zoogloea with embedded bacteria, as well as many free bacteria in the intervals. In figure 25 many of these seem to have been breaking up into débris (these are shown in fainter lines); indeed it was noticed that by allowing putrefaction to take place the appearance of the bacterium termo was always rapidly followed by this result, and finally by the total disappearance of the bacillus under consideration. Perhaps more interesting than the appearance of the rods in all the cultivation fluids, whether from the spinal fluid or from the blood, is the appearance of these filamentous tubes marked e in figures 23 and 24, as proving the identity of the organisms seen in the jelly from the spinal canal, and those developed from cultivation of fluids from the affected animals, as well from the bodies of sheep ticks, as will be seen from what follows.
An examination of the blood alone gave no very satisfactory result. Here and there, however, spore-like bodies were seen; these, however, were neither numerous nor constant; but by inoculating mutton broth with a minute quantity of fresh blood a result was obtained, but not in all instances, exactly identical with that resulting from the cultivation of the spinal fluid. In the course of from twenty-four to thirty-six hours the cultivation fluid was seen to be more or less turbid, and on the microscopic examination of a stained specimen free bacilli were seen in great abundance; a few were also seen in rows. On the third or fourth day mycelia, with spores in their centre or covering their walls, became visible, as well as masses of zoogloeae with numerous embedded bacilli and micro cocci, as seen in figure 23.

e. Mycelium with spores.

The microscopic appearances of the jelly-like substance found in the spinal canal, and the development of the same mycelium,
and spores with motile bacilli from the blood, &c., although not as yet clearing up entirely the life history of these organisms, showed that a new discovery had been made, and that the disease in question was due to the irritation of the nervous system through the spinal cord, in the fluids of which this organism seems to find a suitable nidus for complete development.

The experimental feeding of the sheep on fungoid grasses having given no result (p. 526), the author had but one resource left by which he hoped to determine whether the tick conveyed the disease to the sheep or not, and for this purpose ticks from diseased sheep were introduced into the cultivation vessels containing the mutton broth, and the results were most conclusive. In a few days the fluid became turbid, and was found to contain numerous bacilli or rod-like bacteria, in no respect distinguishable from those got in the fluids from the diseased sheep; and further, that the peculiar filaments with spores in their interior were also seen (figure 24, c).

**Bacillus Choreae Over.—Cultivations from Tick.**

The strawish-coloured mould which soon covered the ticks, when stained, dried, clarified with oil of cloves, and mounted in balsam, presented the appearances seen in figures 24 and 25.

Now this proved nothing beyond the fact that the organism was in the tick; but whether the tick received it from the sheep, or the sheep from the tick, was a point yet to be determined, and for this purpose ticks were obtained from perfectly healthy sheep and treated in the same way, and the conclusion arrived at was that the organism was communicated by the tick from loupings-ill districts to the sheep, for the same organism was found to be developed, but not quite so quickly, in the cultivation as in that containing the tick from sheep suffering from loupings-ill.

This last experiment, repeated over and over again, proved the fact that the ticks experimented with contained the spores of the organism, and were capable of infecting sheep; and that the reason that all sheep were not infected was
simply the fact that many sheep were able to resist the invasion of the organism, or suffered so slightly that they were not observed to be ill.

The infecting organism may be received in two ways:—firstly, by the infected tick fixing itself in the skin, thus directly inoculating the higher animal; secondly, by the ingestion of ticks—which in their earlier stages abound in the grasses—the organism gains access into the system, particularly if any portion of the mucous membrane of the digestive apparatus be abraded.

Many sheep even badly affected recover from looping-ill, and it is fair to conclude that the organism has but a transient effect upon many others; that in fact, as is the case with other diseases, many are able to throw it off, and are most probably by this inoculation rendered proof in many or even the majority of instances against any further infection. This conclusion is borne out by a circumstance well known to flockmasters and shepherds, namely, that sheep removed from a district free from looping-ill are much more liable to take the disease than those reared in "looping-ill districts."

If the reader will refer to page 295, he will find the above deduction is confirmed by French experimentalists on external anthrax.

In order to complete the series of experiments, it was necessary to inoculate mutton broth with the blood and spinal fluid of healthy sheep; and this was repeatedly done, and in every instance with no result, the broth remaining perfectly clear and free from organisms at the time these sheets are going to press, or more than three months after the healthy spinal fluid had been introduced into the mutton broth.

The Anti-Vivisection Act being a bar to the experimental inoculation of animals without a license, and owing to the difficulty of obtaining a liceuse, it has been hitherto impossible to determine whether the disease can be inoculated from the tick, or directly conveyed from one sheep to another,—that, in fact, it is a truly infectious disease; and the problem must still remain unsolved until a future period. If found to be inoculable from the tick to sheep, or from one sheep to another, preventive inoculation with attenuated virus will then have to be considered.

An endeavour to cultivate from the jelly obtained from the
The parks were all in rough grass. Next year he bought some cattle, and far more the following year; ate, cut down, and even burned the old grasses; drained and limed the parks, using six tons of lime per acre to the light and eight tons to the heavy land. He continued to eat, cut, and burn down the grasses as bare as he could, and both the "louping-ill" and the ticks became scarcer and scarcer. The third spring after he entered the farm it was very cold and sleety up to and after the "cutting" time. Ticks were very much scarcer than they had been before, and louping-ill was very much diminished with him, whilst on other farms it was, as might have been expected from the state of the weather, very bad. He thought, but wrongly, as he has now found out, that the wet, coarse weather was the cause of the scarcity of the ticks.

In six years both louping-ill and tick had both almost entirely disappeared—an odd one now and then—and he has had scarcely any since.

He has kept extra stock, both of cattle and sheep, during summer. The number of cattle kept has increased from forty to one hundred and twenty, which were kept during the summer of 1881. The cattle are sold about October, but about thirty head are kept on the hills during winter, part of them being tied at night. Last year Mr. Nichol stated, "You may believe the pastures were eaten to the bone." During our visit, however, we found that the grasses were more luxuriant and of much better quality than on any neighbouring land.

When he first entered the farm, the land kept twenty-three score of sheep; it now keeps thirty score, besides the extra cattle.

Mr. Nichol stated he had been a shepherd for forty years before becoming a farmer; that he never heard of artificial food being given to hill sheep until 1860. Since then, when the sheep have been unable to graze for frost and snow, he has fed artificially upon four different occasions, with half a pound of corn daily, when the hay was done, for from four to eight weeks, or until the grass came, and found the sheep to do well during the ensuing summer, and did not require any artificial feeding during the following winter, unless it was a bad one. When so fed the sheep came off the hill better in spring, although cattle had been on all winter.

Braxy still prevails from October to January.
Mr. Nichol has held the neighbouring farm, Crosslee, for one year; both lousing-ill and tick are on it. He put seventy head of cattle on in the summer of last year (1881), but four of them were poisoned with some sheep-dip left on by the last tenant, so he became frightened and sent them to Newborough. He has twenty-six on now, and intends to have more, and has no fear but that he will abolish both lousing-ill and tick.

There is a strong prejudice amongst even the most enlightened sheep-farmers and shepherds against all artificial feeding of hill sheep during winter, some even going so far as to object to give hay during the coarsest weather, when the ground is deeply covered with frozen snow, and the animals actually dying from the want of food, upon the ground that by being fed upon hay or corn the sheep are made soft and incapable of standing the vicissitudes of the weather. Mr. Nichol very quaintly remarked, "Those who can afford to let their sheep die, do so, but I cannot afford this, so give corn."

One farmer whom I know very well congratulated himself that his heavy loss had taken away all his weakly sheep, and he had now a good strong stock to breed from, stock that would stand anything, even starvation.

One moment's rational consideration of this matter would open the eyes of even the most prejudiced, and convince them that starvation never leads to strength, but to the converse condition, and that a strong healthy stock, although able to live through a hard winter without any food but what they can scrape up, are rendered weak and debilitated; and that the mortality amongst the ewes is enormous during the lambing season, that many dead lambs are brought forth, and that where both mother and offspring survive, the latter often dies from starvation, the ewe being unable to afford it its natural sustenance. It must also be borne in mind that exhaustion of soil, micro-fungi on grasses, ticks, poverty, and lousing-ill are co-existent.

In conclusion, I would earnestly recommend all who may read these observations to carefully consider the suggestions laid down, to increase the number of their stock, and thus utilise that which, if left on the ground, becomes a source of mischief not only in itself, but by affording a cover and harbour for
parasites, which I think have been proved to be the source of enormous losses.

With regard to the ked, Melophagus ovis, found upon all sheep, and having no connection with the disease under consideration, it was discovered that those removed from sheep suffering from loping-ill contained the germs of the organism, and that it could be cultivated as readily as that of the tick itself, whereas, when it was removed from sheep healthy and not upon loping-ill land, no results were obtained, although several experiments were made.

NEURITIS—NEURALGIA.

Inflammation of the Nerves—Neuritis.—When one considers the very delicate organisation of nervous tissue, and the extreme sensibility of the sensory nerves, a most striking fact presents itself,—namely, the rarity or almost total absence of inflammation of the nerves. The nervous substance contained within the cranium, as well as that constituting the spinal cord, is subject to inflammatory changes; but it may truly be said that, except as a result of blood alteration—as in azoturia, where the sciatic nerves, and traumatic tetanus, where the nerves connected with the wound and their neurilemmae, are often found inflamed—neuritis is almost unknown, or, if it does exist, has not as yet been correctly diagnosed.

Neuralgia, or pain in the course of a nerve, and recurring in some few cases at stated intervals, whilst in others the recurrence is very uncertain, is also a disease which is rarely or never met with in the lower animals. I certainly once heard of a case which presented some signs of having neuralgia of the face, but whether it was that or pruritis the practitioner under whose care the horse was placed could not tell. The symptoms were persistent rubbing of the face against any solid object for a certain period each day, with shaking of the head and great restlessness.

The principles of treatment applicable to neuralgic diseases will entirely depend upon the cause. If a nerve leading from a wound be inflamed, then fomentations and emollients must be applied; whilst belladonna should be rubbed along the course
of the nerve, or, if the pain be excessive, morphia may be injected subcutaneously into the tissues of the painful part.

Should it be considered that neuralgic pains arise from a mal- or debilitated condition of the animal generally, then measures must be resorted to which are calculated to restore the body to its normal condition, and in many cases aperients, followed by nervine tonics, such as arsenic, nux vomica, iron, or, where it is deemed necessary to soothe pain, belladonna, stramonium, yellow jessamine, or the bromides, may be administered for a short period. If pain on the course of a nerve threaten to become chronic, a smart blister will be imperatively called for.
CHAPTER XLVI.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(I) DISEASES OF THE RESPIRATORY ORGANS.

Before entering upon the consideration of the particular diseases of the respiratory organs, it will be necessary to point out certain modes of physical examination by which the diagnosis of these diseases is accurately traced.

1. Auscultation.—In its technical sense this term indicates the act of listening to the sounds of the interior by means of the ear applied to the surface of the body.

Auscultation may be practised directly by applying the ear to the part; or indirectly through the medium of an instrument called a stethoscope. Generally direct or immediate answers every purpose; and in veterinary practice, at least, indirect or mediate auscultation is seldom practised. Auscultation, discovered by Laennec, was introduced into veterinary practice by Delafond and Leblanc.

Many of the sounds characteristic of abnormal conditions in the human being are not heard in the lower animals; hence auscultation, as well as percussion, is less satisfactory in the hands of veterinary surgeons than in those of the physician. There are various reasons for this, and not the least of them is the fact that the thoracic walls of man are much more thinly covered with muscular tissue than those of the lower animals. Again, a large portion of the thoracic cavity in our patients is covered by the scapulae, which form insuperable barriers to examination. These, in addition to the movements of the panniculus carnosus, the horizontal position of the body, oblique arrangement of the diaphragm, the pressure of the digestive
organs, and very often the restlessness of the patient, render this method of examination much less satisfactory than it otherwise would be; but, notwithstanding all these drawbacks, auscultation is of immense advantage, and by it we are enabled to arrive at conclusions that would otherwise be impossible.

To become familiar with the knowledge to be acquired by auscultation much time and labour must be devoted to it, first on healthy, and afterwards on unhealthy animals; in fact the ear must be trained by long experience.

The stethoscope can be bought at any instrument maker's, and the simpler it is the better. In applying it to the chest, its funnel-shaped end is to be accurately and firmly applied to the surface, and the opposite end in perfect apposition to the ear.

When immediate auscultation is practised, care is to be taken that the ear be accurately applied to the skin, or if the state of the surface does not admit the ear, a single fold of a thin cloth only should be allowed to intervene, as the rubbing of two folds or surfaces may create a sound and puzzle the examiner.

2. Percussion.—This process consists in striking upon the surface with the view of eliciting sounds, by the nature of which an opinion may be formed of the conditions of the parts beneath. Like auscultation, percussion is either immediate or mediate. The former was employed by Avenbrugger, and the latter invented by M. Pierry, who gave the name of “pleximeter” to the intervening body.

In immediate percussion, the ends of the fingers are brought together and supported by the thumb, and the parts are struck perpendicularly to the surface, or the parts may be rapped with the knuckles of the closed hand, the force of the blows being regulated by the depths of the parts to be examined, and the size and delicacy of the animal. In the cat or dog gentle blows with the tip of the middle finger are generally sufficient.

In mediate percussion, the pleximeter is generally a flat, oval, or circular piece of ivory or gutta percha, or the left index finger of the operator, which is certainly the most convenient and best intervening body which can be had.

M. Poisson of Paris recommends that percussion should be performed by means of a common sewing-thimble placed on the middle or fore finger, so as to include a small portion of air between the end of the finger and that of the thimble. The intensity of sound elicited is said to be thus greatly increased.
Some operators substitute a small hammer for the fingers, the head being made of wood, ivory, or metal, with its percussing surface covered by a softish and somewhat elastic substance, as felt, caoutchouc or gutta-percha. The more satisfactory method, and the best and simplest, is immediate percussion by the tips of the fingers or knuckles; the part percussed to be unclothed, and struck perpendicularly to its surface, otherwise the character of the sound will sometimes be confusing.

3. Palpation.—Touch is useful in the diagnosis not only of chest diseases but of many other ailments. By this method we detect tenderness, heat, coldness, fluctuations, tumours, and a variety of conditions indicative of disease.

If an animal be affected with pleurisy, firm pressure in the intercostal spaces will cause wincing, grunting, or even groaning.

4. Measurement is recommended by the French veterinarians. It has, however, found little or no favour in this country, as it is considered that an amount of disease sufficient to alter the relative size of the sides of the chest is otherwise determined than by measurement. In the cat, dog, and cow, the intercostal spaces are expanded and dilated in hydrothorax of one side, if of long standing; and in some cases of chronic pneumonia in cattle I have confirmed the observations of Delafond, that one side of the chest is sometimes palpably larger than the opposite side.

Measurement as applied to the chest, says Mr. Gamgee, "consists in the application of a cord or tape to the similar parts of the two sides of the chest, in order to ascertain whether any difference exists in their relative prominence. For the larger animals a tape of three or four feet, and for the smaller of one and a half to two feet, may be employed. One end is placed immediately behind the withers, and the line carried downward to the middle of the sternum, which part is marked by a knot; a second measurement is made from the withers to the eighth rib, or the commencement of the cartilages of the false rib, and similarly marked; a third measurement is made from the lower end of the third rib to the commencement of the cartilages of the false ribs; lastly, the tape may be carried from the posterior border of the shoulder along the middle region of the chest as far as the last rib. The same measurement may then be made on the opposite side of the thorax, care being taken that they be always made at the same stage of the respiratory act, as otherwise false
results will be obtained. It is well, indeed, to measure the different parts after both inspiration and expiration, that any difference in the expansion of the two sides of the thorax may be ascertained."

5. Inspection.—Some symptoms are observed by inspection only—the condition of the visible membranes, the attitudes and movements of the body, the expression of the countenance, the character of the respirations, the degree of fulness, or the converse, of the several parts. In human medicine the state of the larynx can be thus detected by an instrument called a laryngoscope, but owing to the length of the oral cavity, the dimensions of the velum pendulum palati, and the position of the larynx itself, the laryngoscope has not yet been made available for veterinary purposes.

6. "Succussion consists in grasping the thorax between both hands, and shaking it quickly so as to elicit sound. It is only useful when gaseous and liquid matters coexist in the pleura; in such cases, however, a splashing or churning sound may be heard. It will strike every one that this measure is only applicable to the smallest class of animals."—(Gamgee's Domestic Animals, page 537.) I have never practised this method of examination, nor do I recommend it, and here describe it in Mr. Gamgee's own words.

RESPIRATORY SOUNDS.

The respiratory sounds, normal and abnormal, detectable by auscultation, are divided into four classes, namely, Nasal, Laryngeal, Tracheal, and Thoracic.

NASAL SOUNDS.

In the normal condition a soft, to-and-fro, blowing noise, of equal intensity on both sides, is heard when the ear is approached to the nostrils. This sound is increased with exercise, and then bears a resemblance to the sound of a large bellows. There is no sound detectable through the parietes of the nose nor the sinuses of the head except after exercise, when a slight snore may be detected through the first and a murmur in the latter.

In some horses the nasal sound is abnormally increased with
exercise, and can be heard at a considerable distance from the animal, causing the horse to be termed a "high blower." This sound is generally much greater when the animal is gently trotted or cantered than in the gallop, and is louder in the expiratory than in the inspiratory act. The increase of sound arises from flapping or crackling of the nostrils, and has no connection with any disease. "It arises," says General Sir Frederick Fitzwygram, "from powerful muscular development in the part. If a horse so formed be pushed to its speed and continued for some time, it will be seen that it can intermit the noise at its will; and when it really becomes distressed at its pace it will have something else to do than flap about its nostrils, and the sound will then cease altogether."—(Horses and Stables.) I have repeatedly observed that some horses will emit this sound when they are first put into training after resting for a while, but when they are brought into condition the sound entirely ceases, and I have thought that the sound was due to flaccidity of the dilatatores narei muscles. In other horses, again, high blowing is due to a natural narrowness of the nostrils and nasal passages. It never seems to interfere with the horse's usefulness, and, consequently, is not to be considered an unsoundness.

Snoring is diagnostic of polypus, thickening of the Schneiderian membrane, or some other obstruction to the passage of air through the nasal chambers.

A snuffling sound indicates some disease, accompanied by discharge from the nose, as purpura, glanders, catarrh, &c.

Whistling may be due to a tumescent condition of the Schneiderian membrane. This is, however, rare, and may be mistaken for a sound arising in the larynx or even in the lungs, which sometimes so retains its force within the nasal chambers as to lead one to think it originates there. Auscultation of the several parts will, however, enable the practitioner to determine where the sound originates.

Sneezing or snorting indicates an irritable condition of the Schneiderian membrane, and is present in many cases in the early stages of catarrh. Sometimes I have seen it very persistent after the subsidence of the catarrhal symptoms, or existing independently of any apparent disease, coming on in paroxysms when the animal has been at work. One fit of sneezing has
followed another, causing the animal a deal of distress. Steaming
the head has succeeded in allaying it in some instances, whilst
in others it has been necessary to apply a blister to the face.

*Epistaxis*, or bleeding from the nose, occurs as a symptom of
various diseases, such as glanders, purpura, malignant catarhal
fever. It may also be induced by injuries, rupture of the small
nasal blood-vessels during severe exertion, sneezing, or it may
arise from the presence of a polypus. When arising spontane-
ously or from injury, it must be arrested by the application of
cold astringents or by plugging the nostril with cotton wool
or tow. Percussion applied to the nasal region and sinuses of
the head yield in the young horse but an indistinct resonance;
the sound increases with age as the sinuses undergo change.
The presence of pus, tumours, or coagula deadens the sound. If
there be an extensive accumulation of pus, or a large tumour in
the sinuses, the sound is completely deadened, the bone is
painful to the touch, and often bulging in appearance.

**Auscultation of the Larynx—Laryngeal Sounds in Health
and Disease.**

In health there is a faint to-and-fro respiratory sound. In
disease the laryngeal sounds are varied and important; they
consist of grunting, whistling, coughing, roaring, and trumpeting.
Laryngeal sounds, with the exception of "grunting," constitute
unsoundness. If they be of a temporary nature, and due to
irritation or tumefaction of the mucous membrane, pressure
of abscesses or tumours of a removable nature, the unsoundness
may pass away; but if of a permanent character, no matter how
trilling they be, they distinctly indicate unsoundness, not only
interfering with the usefulness of the horse for the time being,
but generally having a tendency to increase in intensity with
age, and often causing a horse to become unserviceable. I do
not mean to say that a whistler or roarer is not fit for work,
but I assert that the infirmity is a drawback, and an animal
so affected is worth less money in the market.

1. *Grunting.*—If a horse, when struck at or suddenly moved,
cisses, during expiration, a grunting sound, it is called a
"grunter." Such a sound may or may not have any connection
with disease of the larynx. A horse will grunt with pain when
suffering from pleurisy, pleurodynia, and other diseases. Some horses habitually grunt when struck at or moved suddenly. A great number of cart-horses are so affected, and big horses of all breeds are very apt to be grunters, whilst they may be quite sound in their wind. Horses with heavy jaws and ill-set necks often emit this sound; and again any horse may do it if it has been fed for a time with bulky food. The sound is always to be regarded with suspicion, and the animal further tried for its wind, as it generally accompanies roaring or whistling. If the grunter, however, stands the tests used to detect roaring, without making any noise in its breathing, it may be considered sound.

2. Whistling.—This sound is of two kinds, a soft or moist and a dry or hard whistle.

Soft whistling is due to acute laryngitis, when a considerable increase of mucus has taken place, and when the mucous membrane is temporarily swollen. When due to the presence of mucus it partakes more of a wheezing sound, and is generally diminished when the animal coughs. The sound arising from tumefaction of the laryngeal mucous membrane is greater during the inspiratory than the expiratory act. It is very similar in character to the dry sound to be described; but in addition to the sound, symptoms of catarrh, fever, or acute irritation of the larynx are present. This sound indicates a temporary unsoundness, and in many instances it is unsafe to pronounce a decided opinion for several days or even weeks after the subsidence of other symptoms. In such instances the mucous membrane has undergone some degree of thickening; there is relaxation of the vocal cords, a want of tone in the larynx generally, that require some time to overcome. It is impossible to pass an animal of this kind as perfect, and it would be unwise to give a decided opinion until all abnormal sound has disappeared.

Dry whistling.—This sound has been generally looked upon as a modification of roaring. I am, however, of opinion that whistling and roaring are due to different pathological conditions of the larynx, and that they may exist independently of each other; that roaring does not always terminate in whistling, nor whistling in roaring.

Whistling, like roaring, is a sound emitted more particularly during inspiration, and is due to a diminution of the calibre of the larynx, or sometimes trachea, owing to a permanent thicken-
ing of the mucous membrane, distortion of the neck by tight
reining, the presence of an immovable tumour in the trachea,
or by any cause which diminishes the area of the passage of
the air to and from the lungs. Whistling, although loudest
during the inspiratory movement, is by no means always absent
during the expiratory act; careful auscultation is, however,
necessary to detect it. If entirely absent during expiration,
the seat of the lesion causing it is to be looked for
in the larynx or upper part of the windpipe. Whistling, like
roaring is often traceable to hereditary taint, and is an un-
soundness.

3. Roaring.—This symptom of disease consists in a loud un-
natural sound emitted during the inspiratory act. Roaring is
sometimes symptomatic of acute laryngitis, and then only indi-
cates a condition of temporary unsoundness.

The cause of roaring is, however, generally found to be due
in the majority of cases to atrophy and fatty degeneration of the
muscles of the larynx. The origin of the paralysis is involved
in some mystery; but it is generally accepted by veterinarians
that, inasmuch as it is generally confined to the left laryngeal
muscles, the explanation is to be found in the fact that the
recurrent or ascending laryngeal nerve on the left side leaves
the pneumogastric further back than on the right, and winds
round the posterior aorta; whereas the right is given off
opposite the first rib, winding round the dorsal artery, and
consequently the left nerve is more apt to be implicated in any
disease of the chest than the right. This explanation is unsatis-
factory on many accounts. 1st. Roaring is not a common sequel
to pulmonary disease: 2d. It is not an accompaniment of thoracic
disease, which would most certainly be the case if the nerve
were implicated in an inflammatory affection: 3d. Many roarsers
whose history has been known from their birth have never
suffered from any chest affection, nor indeed from any disease
beyond a common cold, and sometimes not even from that slight
ailment: 4th. Mares and ponies are less often affected with
roaring than large geldings and stallions, but are quite as sus-
ceptible to chest diseases; and lastly, dissections have failed to
discover any change in the nerve trunk itself, although the
animals dissected have been confirmed roarsers for years previous
to their death.
It is very true that division or ligature of either of the recurrences will be succeeded by roaring, and tumours involving the recurrences may cause the same symptom; and Dr. Warburton Begbie says that "no more interesting variety of local paralysis exists than that which is due to the interference with the recurrent or motor laryngeal nerve, produced by an aneurism of the arch of the aorta, or by a cancerous mediastinal tumour. Well-marked atrophy of the muscles of one side of the larynx has, under such circumstances, been found." But in the form of disease involving the laryngeal muscles, which commonly causes roaring, there is no change in the nerve itself, nor can the loss of motor power be traced to pressure upon the nerve trunk by any tumour, aneurism, or adventitious substance.

The disease of the muscles is, however, essentially nervous in its origin, and may, I think, be classified as a form of wasting palsy—paralysis atrophica—originating in the laryngeal muscles themselves. Wasting palsy is defined by Dr. William Roberts, in Reynolds' *System of Medicine*, to be "an atrophic degeneration of certain groups of muscles, independent of any antecedent loss of mobility, or of any metallic poisoning."

I have already stated that the atrophic change is usually seen on the left side of the larynx. It, however, by no means follows that the muscles of the right side are entirely free from disease; indeed, in many instances, they distinctly partake of the atrophic change, though to a less extent.

Why the change is greater on the left than on the right side, is one of those things for which no more satisfactory explanation can be given, than why the ulcers of glands are oftener seen in the left than in the right nostril.

Roaring is generally gradually developed. At first, the sound may be intermittent, and days or even weeks may elapse during which the animal may make no noise, although put to severe exertion, as if the muscles had, at the time the sound was emitted, been debilitated from some ephemeral disturbance of nutrition. As the loss of muscular substance progresses, there is a corresponding and permanent loss of power, and what at first was intermittent is now a permanent infirmity. This intermission of the sound is not, however, the ordinary method by which the disease manifests itself. More commonly the noise or roar, slight at first, gradually, but often very slowly, increases in
intensity, thus marking or indicating the progress of the muscular change, and inability to dilate the laryngeal opening.

Causes.—Putting aside all exciting causes of alteration of the air passages, to be hereafter mentioned as causes of roaring, I think that laryngeal muscular atrophy is due to hereditary predisposition; and it is a well-known fact that certain breeds, the produce of certain sires, are nearly all roarsers. I have repeatedly observed this, not only in racers, but in other breeds of horses. Indeed, I know one breed of Clydesdales which are nearly all roarsers, both mares and horses. Horses and geldings are, however, more liable to become roarsers than mares, which seldom, except where the hereditary taint is very strong, become roarsers. Small ponies are scarcely ever affected, although they are subject to colds, laryngitis, and pulmonary diseases.

A horse predisposed to become a roarer generally suffers from laryngeal irritation from trivial causes, and usually the infirmity appears after repeated attacks of cold and sore throat.

Other causes of Roaring.—Concluding that the majority only of cases of roaring are due to the condition described, it is necessary to mention that the sound may arise from other and incidental conditions which, although not so frequent, are quite as important.

Roaring may be due to disease of the nose, nasal polypi, depression of the nasal bones from previous fracture (see Principles and Practice of Veterinary Surgery), osseous tumours in the nostrils; closing of one nasal chamber by false membrane or disease of the bones; tumours on the posterior nares, called "bellowes" by horse-couplers, falling into the glottidean opening, causing intermittent roaring; constriction of the trachea; tumours in the thoracic cavity; distension of the guttural pouches; disease of the pharyngeal and parotidean lymphatic and salivary glands; tight reinning; fractures of the tracheal rings, or any cause of distortion of the larynx.

In addition to the sound emitted during inspiration, the roarer generally has a cough which is diagnostic, being a loud, harsh, dry sound, half roar, half cough; and the generality of roarsers are also gruneters. It will also be found that the sensibility of the larynx is diminished in confirmed roarsers, and that consequently it is difficult to make them cough in the ordinary way by pressing the larynx. In testing a horse for its wind, it is usually the
practice with some to place it against a wall, and threaten it with the whip; if it grunts, it is further tested; if not, it is merely made to cough by pressing the larynx, and if the cough has a healthy sound the animal is generally passed sound.

This plan is not always satisfactory, and the better way is to have the animal galloped, or if a cart-horse, to move a heavy load some little distance, when, if it be a roarer, it is sure to make a noise.

Treatment of Roaring.—If the sound can be traced to any removable cause, the practitioner knows what to do, but the removal of the causes of the form of roaring generally met with is, however, a matter of great importance. Many experiments have been tried; and in some instances the application of blisters, or the actual cautery, to the skin of the laryngeal region, has succeeded, not only in arresting the progress of the atrophic change in the muscles, but in materially improving their strength and tone; but in order that this may prove effectual, the animal is to be treated in the very earliest stages of the disease. In addition to "firing," I have only to suggest that the chlorate of potash is worthy of trial, as it is found to have some power in arresting fatty degeneration.

In very bad roaring the sound may be modified by pads attached to the bridle and fitted over the false nostril. These pads regulate the quantity of air taken in at such inspiration; for it is observable that when a roarer is pushed in its work or paces, that the nostrils dilate greatly, thus admitting a large volume of air, which by its weight and pressure causes a further falling in of the arytenoid cartilage and an increased constriction of the laryngeal opening. If this method be inefficient, tracheotomy is to be performed, and the tube kept in the trachea for the remainder of life. Excision of the left arytenoid cartilage (presuming that the left muscles are atrophied) has been suggested by Günther of Hanover, and has, I believe, been more or less successfully carried out. The operation is to be performed by making an incision through the skin into the superior part of the trachea, the collapsed cartilage seized by forceps or tenacula, and excised by means of a pair of scissors.

It will be apparent that a bad roarer, no matter what the means may be by which the sound is modified, is only useful for slow work; and lastly, I have always observed that confirmed
roarers become bad thrivers, and often succumb to trivial diseases.

Roaring being due to a progressive disease, it is necessary that the veterinarian should reject as unsound every animal which makes the slightest roaring or whistling sound in its breathing.

**Cough as Indicative of Disease.**

Cough is the sound produced in the larynx by the violent expulsion of air from the lungs, and is symptomatic of various diseases. Cough is divided into dry and moist.

*Dry cough* is divided into short, hacking, hollow, broken-winded, and spasmodic. The dry cough is symptomatic of irritation and dryness of the respiratory mucous membrane. In the early stages of laryngitis it is loud and long, becoming afterwards rasping and then moist. In chronic disease of the larynx it is loud, roaring, and often hollow. In the early stages of bronchitis it has a hollow metallic sound; it afterwards becomes moist, and is more or less painful throughout the disease. In pneumonia the cough is short, seems as if proceeding from a solid organ, and is accompanied in the later stages by a rusty, tenacious expectoration.

The *cough of pleurisy* is dry throughout, is painful, hacking, sometimes as if cut in two, the animal being seemingly afraid to complete the act by one effort.

The *broken-winded cough* is at first spasmodic, becoming, as the disease advances, feeble, short, and single, the animal being unable to relieve itself by the action of the chest and lungs; hence the suppressed cough becomes diagnostic.

The *hollow cough*, a sepulchral sound, varying in intensity, indicative of chronic disease, and on this account is termed a "chronic cough."

The *moist coughs* indicate an inflamed and humid condition of the respiratory mucous membrane.

There are various other kinds of coughs associated with diseases of the heart, digestive organs, and the process of dentition; these are valuable as aids to diagnosis, when studied in connection with other symptoms. They are mostly dry coughs.

Horses with narrow, shallow chests, weak loins, and long legs are very generally predisposed to cough from very trivial causes.
TRACHEAL SOUNDS.

Except at its entrance into the chest, the trachea yields no sound. At this point, however, a blowing sound—tracheo-bronchial respiration—can be heard, more prolonged during the expiratory act. In disease this may be increased. When the bronchi contain much mucus or other fluid, a moist rattle—mucous rale—may be heard, accompanied by a wheezing, gurgling, or spumous or frothy sound.

THORACIC SOUNDS.

The thoracic sounds are divided into pulmonary, pleural, and cardiac. The pulmonary sounds are of two kinds, namely, the vesicular and the bronchial sounds.

1. Vesicular, also called the respiratory murmur, is heard during both inspiration and expiration. During the inspiratory act it is a soft diffused murmur of a gentle breezy character: slightly harsher and more hollow during expiration, and not above one-fourth the length of that during inspiration. It is caused by the entrance and expulsion of air to and from the terminal portions of the bronchi and air sacs. The intensity of this sound is increased with exercise or other causes of quickened respiratory movements, as fever; is louder in chests thinly clothed with flesh; stronger in the young than in adults, hence, when strong, it is called “puerile”; it is also louder when the stomach is empty. Puerile respiration depends upon the smaller size of the air vesicles, and the greater elasticity of the lung tissue; in the very old the murmur is scarcely perceptible, and is called “senile.” Senile respiration may also result from slow breathing, or any cause which obstructs the entrance of air into the lungs. If either modification is present to the same extent in the same region of both sides of the chest, they indicate no other condition than the natural ones above indicated; but if the murmur is puerile on one side and senile or absent on the other, the first indicates a compensating action of that lung, supplementary to diminished action in the other. The vesicular murmur is best heard in the superior portion of the lower third of the chest, from behind the elbow and shoulder to about the ninth rib, whence it diminishes in force,
and is altogether lost over the sixteenth. In the inferior part of the chest it diminishes at the seventh, and is lost at the tenth rib. On the left side it is mixed in the lower and anterior regions, immediately behind the shoulder, with the sounds of the heart.

2. The Bronchial or Tubal sound resembles the blowing of air quickly through a tube; it is higher in pitch than the vesicular murmur, and more rapidly evolved. It is nearly as prolonged during inspiration as expiration, with a distinct interval between the two. This sound is distinct over both the middle and upper thirds of the chest; loudest immediately behind the scapula and caput magnum, or the nearer we can approach the ear to the bifurcation of the trachea and larger bronchial tubes; diminishing in intensity to the twelfth rib, where it is superseded by the vesicular, and entirely lost at about the seventeenth rib. It also diminishes in intensity as it approaches the upper part of the lower third of the chest, where it becomes lost in the vesicular sound. The tubal sound becomes diagnostic of disease when it is heard in the inferior portions of the chest.

In the ox, the bronchial sound is heard much lower down in the right side, owing to the large tube which passes to the anterior lobe of the right lung.

The true thoracic sounds are very often complicated with abdominal rumblings or gurglings, due to the movement of food, fluids, and gases within the alimentary canal; these are loudest in the posterior part of the chest, are irregular in their occurrence, and bear no relationship to the respiratory movements. A little practice will soon enable the student to distinguish these from the respiratory sound.

Percussion.—The sound obtained by percussing the healthy chest is loudest over those parts where the bronchial sounds are best heard, except indeed in those parts most thickly clad with muscular tissue. On the left side the resonance is very clear immediately behind the shoulder to the twelfth or thirteenth rib, where it gradually diminishes. If the parts are here struck forcibly, the intestinal resonance may be induced.

Mr. Percivall has pointed out what may be easily verified in practice, that the sound along the right superior region grows louder from the posterior border of the shoulder to the last rib, whilst on the left it gradually diminishes on the same line.
This increase of sound on the right side is due to a resonance from the arch of the colon. If the blows are light, this sound is not brought out, and when heavy, it is more of a tympanitic character, resembling that of an emphysematous lung. Along the middle region louder sounds are elicited than either above or below, more particularly between the fifth, sixth, seventh, and eighth ribs, from whence it diminishes to the fifteenth, and then becomes tympanitic or abdominal on the left, and dull on the right side, owing to the opposition of the liver. In the inferior part of the chest the sound is weak, but clear, from the fifth to the eighth rib on the right side, where it becomes dull, responding to the liver; whilst on the left side the resonance is almost absent over the fifth, sixth, and seventh ribs, opposite to the heart; it becomes clearer over the eighth, behind which it loses its intensity, and is lost at about the thirteenth rib.

MORBID SOUNDS.

The morbid sounds indicative of diseases of the respiratory apparatus elicited by auscultation may be divided into bronchial, pulmonary, and pleural.

BRONCHIAL SOUNDS.

These are of two kinds, namely, 1st. Dry; and 2d. Moist.

1. Dry sounds are subdivided into large and small, or rhonchus and sibilus.

(a.) Rhonchus, a hoarse, sonorous murmur, sometimes of a humming, cooing, or snoring character, compared to the bass note of a violin or cooing of a pigeon, especially marked during expiration, but coexistent with both movements, and due to a narrowing of some part of the larger bronchial tubes. It may be heard at the front of the chest very plainly, as well as behind the shoulder. It is sometimes caused by portions of viscid mucus adhering to and obstructing the larger tubes, acting as vibrating tongues as the air passes by them. If the adherent mucus be removed by coughing, the sound may disappear for a time, and then reappear; when not removed by coughing, it may be due to tumafaction of the bronchial mucous membrane; and
if permanent in a given spot, it may arise from the pressure of a tumour or other cause which may flatten an air-tube. Rhonchus essentially belongs to the larger tubes, denoting partial narrowing; is a dry sound, and, if uncomplicated, indicates a condition of no great danger. It is also called vibration, sonorous rhonchus, and sonorous rale, and is generally associated with bronchitis.

(b.) _Sibilus, Sibilant Rale, Sibilant Rhonchus._ A high-pitched whistling, hissing, clicking, wheezing sound of variable intensity and duration, coexistent with both respiratory movements, but more especially marked during inspiration, arising from tumefaction or accumulation of viscid mucus in the small bronchial tubes. I once heard a dairyman call this a "chaining sound," from its resemblance to rustling of an iron chain. It is associated with bronchitis situated in the smaller tubes, and is best heard over those regions where the vesicular murmur is most audible in health. It indicates greater danger than rhonchus, and if present over a large surface of both sides, a condition of great gravity.

2. Moist sounds.—The dry, bronchial sounds are succeeded in bronchitis by moist ones, termed rales, rattles, or bubbling sounds.

(a.) _Mucous Rhonchus or Rale._ The bursting of bubbles of some size, unequal and varying in number, modified by coughing and expectoration, coexistent with both respiratory movements. It is due to the bubbling of air through liquid—mucus, blood, or pus—in bronchial tubes the size of a crow quill, heard in those regions where the tubal sound is most apparent in health. Succeeding dry rhonchus, it indicates the moist stage of bronchitis.

(b.) _Small bubbling Rhonchus or Rattle, subrepitant or submucous Rales or Rhonchi_, succeeding sibilus, coexistent with both movements, but loudest during inspiration, and due to the bubbling of air through a more or less viscid fluid in the minute bronchial tubes at their peripheral distribution; heard in bronchitis affecting the smaller tubes, and during the resolution of pneumonia.

(c.) _Gurgling Rattles, cavernous Rhonchi or Rales._ The bursting of bubbles, obviously of a large size, with a hollow, gurgling sound, or a metallic sound if the bubbles be small, coexistent with both respiratory movements, is associated with vomices or
excavations from tubercle, dilatation of bronchi, pus in pleura, with a bronchial fistula and deliquescence of gangrenous lung structure.

PULMONARY SOUNDS.

1. Crepitations.—Crepitant rale or rhonchus; compared to the sound produced by rubbing slowly and firmly between the finger and thumb a lock of one's hair near the ear, or to the crackling of salt when scattered over hot coals. It is heard during inspiration only, and indicates the primary stage of pneumonia. "Probably due to the sudden expansion of delicate tissue, altered in its physical properties by the inflammatory state, and which probably undergoes minute ruptures."—(Aitken.) This sound is best heard in the lower third of the chest, replacing the vesicular murmur. After continuing for a short period it may disappear, and the vesicular murmur return, indicating the resolution of the inflammation. Usually, however, the crepitation becomes fainter and fainter, and is substituted by—

2. Tubal or Bronchial sound.—The tubal or bronchial sound, when heard over the inferior portions of the thorax, indicates some degree of consolidation or hepatisation of the lung tissue. It shows, in fact, that the minuter ramifications of the bronchi and air vesicles have become impervious to air, by the pressure of an exudate within and upon their walls, and that the larger tubes of the part are still pervious. In health, both vesicular and tubal sounds are emitted by all parts of the lung tissue, but can be detected by auscultation in certain parts only. For example, the tubal sound is so loud in the upper and anterior parts of the chest, as to mask or hide the vesicular murmur to a great extent; and, conversely, the vesicular murmur being loudest at the inferior portions, masks or renders inaudible the tubal or bronchial sound. When, however, those portions of the lungs, namely, the minute tubes and air vesicles, are rendered impervious—the larger sized tubes still remaining pervious—it naturally follows that the sound emitted by air passing in and out of the larger tubes now becomes audible.

In many instances, however, the tubal sound continues for a short time only, and is succeeded by—

3. Absence of sound.—When this occurs it indicates that the exudation is excessive in quantity, that the larger as well as the
smaller tubes have been rendered impervious, or that effusion
has taken place into the cavity of the thorax.
Consolidation of the lung tissue, and the presence of fluid in
the thoracic cavity, can be recognised the one from the other—
(1.) By the previous character of the sounds; and (2.) By the
manner in which the absence is marked. In hydrothorax the
termination of the area of absence of sound is sharply defined
superiorly; above the "water line" the pulmonary sounds
are generally exaggerated. In consolidation the area of absence
of sound has no sharply defined limit; at the lower parts of
the chest, and for some inches upwards, there may be no sound at
all; then faint tubal sounds are heard, which increase in intensity
as the ear is moved upwards along the thoracic walls. Now
and then a blowing sound is heard in consolidation of the lungs,
confined as it were to the supercilies of the lung, indicating
hepatisation of the deeper-seated portions of the organ, leaving
the subpleural parts still pervious. My experience leads me to
the conclusion that this superficial blowing sound is a bad
symptom, indicating a creeping pneumonic inflammation, having
a tendency to a fatal issue.

4. Secondary crepitations.—Consolidation, as above described,
is succeeded by the breaking up and absorption of the exudate.
This process is marked by the advent of crepitations of a
bubbling nature, slowly evolved, few in number, dissimilar
and irregular in occurrence, more audible during inspiration than
during expiration; they mark the resolution of pneumonia, and
are succeeded by the natural sounds more or less modified. Such
are, then, the sounds of pneumonia. They are subject to modifi-
cations, and to be variously mixed one with the other during
the various phases of the disease.

PLEURAL SOUNDS.

1. Friction sound.—A grazing, rubbing, grating, creaking,
irregularly jerking, superficial noise, heard more particularly in
inspiration, or in both respiratory acts. It results from the
rubbing together of the two opposed surfaces of the pleura, chiefly
heard at the lower part of the chest, where the pulmonary organs
have the greatest freedom, and is indicative of dryness of the
serous surfaces, or any cause of roughness upon them. This
sound is succeeded, when hydrothorax occurs, by—
2. *Absence of sound* in the inferior part of the thorax, reaching to a certain line, above which the respiratory sounds are heard. As the fluid accumulates, the absence of sound ascends. In some cases of hydrothorax one or two other sounds are heard, namely, metallic tinkling, and a gurgling or splashing sound. These sounds are only heard when gas or air and fluid coexist in the pleural cavity. The metallic tinkles may occur from drops of fluid, imprisoned in false membranes, falling from the roof of the pleural cavity into the liquid beneath, or may result from the bursting of bubbles of air or gas on the surface of the liquid.

In the horse the pleural sounds are less distinct than in the ox and dog.

The sounds termed bronchophony, pectoriloquy, egophony, and amphoric resonance, produced by modifications of the voice during articulation, do not apply to any morbid sounds heard in the lower animals.

**Cardiac sounds.**

If the left (near) fore leg be extended, and the humerus pulled forward as far as possible, the sounds of the heart can be made out if the ear or stethoscope be applied to the left side.

The sounds of the heart in health are two in number: first, a longish, dull sound, then a sharp sound, succeeded by a pause, and then the recurrence of the sounds in a regular and uniform manner, provided the animal is not excited nor in any way disturbed. The first sound coincides with the hardening of the ventricles, the complete closure of the auriculo-ventricular valves, and the opening of the arterial orifices; it is caused principally by the sudden distension of the ventricles, and is of the same nature as the noise made by all muscles in contracting against a resistance.

The second sound is undoubtedly due to the sudden closure of the sigmoid (semilunar) valves at the conclusion of the ventricular contraction. This has been proved by experiments on living animals, the sound being destroyed by hooking back the semilunar valves.

The impulse of the heart may be felt by placing the hand directly upon the left side of the chest, immediately behind the elbow. It is very distinct in flat-sided and lean animals, less
DISEASES OF THE RESPIRATORY ORGANS.

distinct, or even entirely absent, in round-chested and fat ones. Diminished impulse, when not due to the above cause, indicates feebleness of the heart's action from disease, as fatty degeneration of its muscular tissue; hydrops pericardii, when the apex may be prevented by the effusion from coming into contact with the thoracic wall; or it may arise from weakness of the system generally, attenuation of the cardiac walls, and dilatation of the cavities. Emphysema of the lungs may also diminish the impulse, the enlarged lung overlapping the heart; and adhesions of the pericardium to the pleura of opposite sides may bind down the heart so that the impulse will not be felt.

The impulse of the heart is temporarily increased by any cause of excitement, fear, exercise, fever, or pain. When excessive it is called palpitation.

Increased impulse, when not traced to the above-named causes, or when it is easily induced, may depend upon organic disease of the heart. It is stronger than natural in hypertrophy of the cardiac walls, and particularly so if such hypertrophy is associated with dilatation. It may, in such cases, be slow, gradual, and double, and this kind of impulse is due to no other condition of the heart; indeed it is one of those few symptoms which throw light upon the condition of parts within, for, notwithstanding much observation carefully recorded, we are bound to confess that, unless cardiac diseases be aggravated, we are unable, either by the character of the sounds or impulse, to diagnose them with that certainty arrived at by those who practise on the human patient.

MORbid SOUNDS.

1. A to-and-fro friction murmur, synchronous with the heart's movements, indicates pericarditis or pericardial effusion.

2. A bellows murmur with the first sound indicates mitral insufficiency; stricture of aortic orifice; disease of the aortic valves, or deposits on the ventricular surface of the mitral valves; or it may depend upon an altered condition of the blood itself, as in anaemia, in which case it resembles a churning sound, heard also in the large veins and arteries. These anemic murmurs vary with the condition of the blood. Sometimes there is a continuous hum heard at the base of the jugulars, and to which the French have applied the term "bruit de diable."
3. A bellows murmur with the second sound indicates aortic insufficiency; roughened auricular surface of the mitral valves, or mitral obstruction. The most common sound heard in the horse is a murmur masking or hiding the second sound, and indicating semilunar insufficiency. When the murmur is double, occupying the periods of both cardiac sounds, it indicates mitral obstruction and insufficiency.

The sounds of the heart may be seemingly intensified by consolidation of the lungs and by hydrothorax, and diminished by emphysema of the lungs. In some instances of consolidation the sounds may be more distinctly heard on the right than on the left side: this indicates hepatization of the right lung, with compensating dilatation of the tubes of the left one.

Metallic tinkling, coincident with the cardiac impulse, is sometimes associated with the booming sounds of endocarditis.

PERCUSSION IN DISEASE

Supplementary to auscultation, percussion is a valuable aid to diagnosis, more especially of pleural and pulmonary diseases.

1. Increased resonance indicates dilatation of the bronchial tubes and air vesicles; if partial or confined to one side only, and if associated with dulness of the opposite side, increased resonance may merely indicate a compensatory respiratory effort. In such a case the respiratory murmur will also be increased. Augmented resonance is, however, generally associated with decrease or absence of the true respiratory sounds, and accompanied with wheezing, creaking, crackling crepitations, indicative of pulmonary emphysema, as in broken wind, rupture of the air cells, and chronic bronchitis.

2. Diminished resonance indicates consolidation of the lungs, hydrothorax, pleural exudations, tubercles, congestion of the lungs, pulmonary apoplexy, &c. When confined to the inferior parts of the chest, replaced abruptly superiorly by increased resonance, it is diagnostic of hydrothorax. When the dulness gradually disappears, it is indicative of hepatization of the lung tissue, being greatest where the consolidation is most complete.

It is stated that enlargement of the heart is indicated by an increased area of cardiac dulness; for my own part, I have never been able to make this out.
CHAPTER XLVII.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(I.) DISEASES OF THE RESPIRATORY ORGANS—continued.

CATARRH AND LARYNGITIS.

CATARRH.

Synonyms.—Common cold, coryza, a defluxion or running at the nose.

Symptoms.—Catarrh is indicated by sneezing, running from the eyes, redness and dryness of the Schneiderian membrane, succeeded by a discharge, at first thin and colourless, which soon, however, becomes turbid, yellowish-white, and profuse. It is associated with a varying degree of fever, dulness, and debility.

Causes.—Alternations of temperature, hot, ill-ventilated stables, exposure to wet and cold. A strong predisposition to cold exists during the process of changing the coat. Young animals, more especially if newly brought into warm stables, are pre-eminently liable to suffer. In some instances it is complicated with laryngitis, and in all cases, if the animal be neglected, the catarrhal inflammation is apt to spread from the nose over the whole surface of the respiratory mucous membrane.

Treatment.—This is a very simple matter if adopted in time, and consists in placing the animal in a well-ventilated loose box, clothing the body if the weather be cold, feeding upon bran mashes, boiled linseed, and a small quantity of good hay for a few days.

In the early stages the nasal irritation will be much relieved
by making the animal inhale steam, and this is best done by holding its head over a bucketful of hot water, and stirring the water with a wisp of hay. A few doses of nitrate of potash are beneficial in the early stages as a febrifuge and diuretic; if the supervening debility be extreme, tonics and good food are to be prescribed. Some writers recommend that a purgative should be given: this is a practice which cannot be too strongly condemned, as in all catarrhal affections there is a tendency to the spread of the irritation, and a purgative may cause a fatal inflammation of the mucous membrane of the digestive organs; but, provided that the effect of such treatment is not immediately fatal, a simple disorder is rendered complicated and serious, and, should the animal ultimately recover, the convalescence is much more prolonged and difficult. Any undue constipation of the bowels is best combated by laxative food, enemas of warm water, and perhaps eight or ten ounces of linseed oil. If the cough be troublesome the throat may be stimulated or lightly blistered. For the results of catarrh, see Principles and Practice of Veterinary Surgery, page 517, et seq.

**LARYNGITIS.**

*Acute Laryngitis.*—An inflammation of the lining membrane of the larynx, indicated by difficult breathing, discharge from the nose, and febrile disturbance.

*Pathology and Symptoms.*—Laryngitis is not an uncommon nor yet an unimportant disorder, sometimes killing quickly, and at all times a dangerous disease. The gravity of acute laryngitis depends upon the nature, character, and extent of the inflammation. In acute inflammation, embracing the epiglottis and rima glottidis, there is such a rapid and extensive effusion into the submucous tissue, and formation of mucus upon the free surface of the mucous membrane, as to cause almost a total obliteration of the glottal opening, and the death of the animal from suffocation. This rapid effusion into the submucous tissue and swelling of the membranes constitute what is termed "œdema glottidis," and it is to this rapid effusion that the danger to life is due. The respirations become suddenly difficult, the inspiration being particularly prolonged, and attended with a peculiar harsh sound, succeeded
by a short expiratory movement, sometimes, but very rarely, attended by a hoarseness. The animal's nose is protruded, the superior respiratory passages being thus made to approach as near a straight line as possible; the eyes prominent, conjunctivæ red and highly injected, with abundant flow of tears. There is a peculiarly anxious and distressed expression of the face, the alae of the nostrils are dilated, the nasal chambers are reddened, there is a hoarse rasping cough, sweats bedew the body, the legs and ears are cold, the latter often drooping; the animal manifests its distress by frequently stamping with its feet—the fore ones particularly. The slightest excitement aggravates all these symptoms; the pulse, which may at first be hard and full, soon becomes rapid and indistinct—fullness generally remaining; the visible mucous membranes now assume a livid appearance from non-oxidation of the blood; prostration of strength becomes extreme; the animal staggers, finally falls, and dies after a few struggles. The above is a description of by no means a common, but of an aggravated form of acute laryngitis. In many cases the symptoms are much less severe, but they partake of the general character of those above described. There is generally a discharge from the nose, even in the early stages, and the act of deglutition is performed with great difficulty. In some instances this is due to the inflammation extending to the pharynx; in others, however, there seems to be no real pharyngeal complication, for if tracheotomy be performed, the difficulty in swallowing is immediately removed. It appears to me that the difficulty in swallowing is due to the momentary pressure of any liquid or solid upon the inflamed epiglottis, causing increased interruption to the ingress of air. Restore the freedom of breathing by the operation of tracheotomy, and the passage of fluids or solids from the fauces into the pharynx no longer prevents the free ingress of air, and hence the swallowing again becomes easy. In those cases, however, in which the difficulty in swallowing persists, the pharynx is inflamed, and the food is returned into the nose, tinging the mucus with its own colour.

The causes are the same as those of common cold.

Treatment.—In an aggravated case this must be prompt. Inhalation of steam, and hot fomentations to the throat, may be tried for a short time, but if the distress is not speedily relieved,
tracheotomy is to be resorted to. In the milder cases, inhalations, fomentations to the throat, succeeded by blisters, with febrifuges; light, soft diet, warm clothing, comfort, and pure air, constitute the necessary treatment.

It may be observed that when deglutition is difficult, all medicines should be given in the animal's food or water, the latter being abundantly supplied, as enforcement may cause violent fits of coughing, and even suffocation. Belladonna sometimes has a good effect in the earlier stages; it is best given as the extract, placed between the teeth.

This disease is always succeeded by great prostration of strength; and in order to prevent this as much as possible, milk—in conjunction with eggs beaten up, or boiled hard and powdered—should be allowed the animal to drink, alternately with water, gruel, or linseed tea. But none of these should upon any consideration be forced upon it by horning or bottling, for, as I have already stated, this is a dangerous practice, and one calculated not only to excite violent fits of coughing in all diseases of the throat, but indigestion, and disorder of the digestive apparatus in all other ailments, and thus destroy what little appetite the patient might possess.

Sequelæ.—Thickening of the mucous membrane, ulceration of the rima glottidis, atrophy of laryngeal muscles, and follicular growths upon the laryngeal entrance.

Thickening of the mucous membrane is best removed by a course of iodide of potassium and blisters; ulceration of the rima glottidis, by solution of nitrate of silver applied to the part by a sponge fastened to a rod. The follicular growths have been removed by the application of solution of corrosive sublimate—forty grains to the ounce of water; and to prevent the progressive atrophy of the muscles, I would recommend a trial of the chlorate of potash.

Chronic Laryngitis.—(See Roaring.)
CHAPTER XLVIII.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(I.) DISEASES OF THE RESPIRATORY ORGANS—continued.

GROUP—CYNANCHE TRACHEALIS: DIPHTHERIA.

GROUP.

Young cattle, varying from a few weeks to a few months old, are subject, when kept on low, damp pastures, more especially in meadows near rivers, and during the fall of the year, to a form of inflammation of the throat, characterised by the formation of a fibrinous exudate or false membrane of a greyish-white colour, sometimes brown or yellow, extending over the larynx, trachea, and sometimes fauces, or the bronchial mucous membrane.

I have never seen this disease in any but young calves, and in one district only, namely, on the borders of the River Alun, near Mold, Wales. Fowls are subject to croup, and Mr. James Law, in the Edinburgh Veterinary Review, vol. iii., page 216, hints that the carnivora are subject to it.

Croup differs from ordinary catarrhal laryngitis in a most remarkable manner. In laryngitis there is an increased formation of mucus, which is discharged as quickly as it is formed. In croup, an exudative process attends the inflammation in the larynx and trachea, which induces the formation of false membranes, varying in thickness and consistency, some of which being several lines in thickness and very opaque, whilst others are so thin that the mucous membrane is easily seen through them. Some are so firm in consistence that they can be detached for a considerable length without tearing, whilst others are almost diffusent. In colour they vary from a dirty greyish-
white to a yellow or yellowish-brown. If an animal be examined post mortem, after the disease has existed for four or five days, the windpipe and larynx will be lined for a considerable distance, in some places partially only; in other parts the entire circumference will be embraced by the false membrane, forming a complete hollow tube or cylinder.

Some writers maintain that croupous inflammation is a more intense form of inflammatory action than that witnessed in ordinary (catarrhal) inflammation of mucous membranes. Dr. Copland, however, states that subacute or slight inflammatory action may be inferred as having existed in connection with an increased proportion of fibrino-albuminous matter in the blood, whenever we find the croupal productions in the air passages. Neither of these views seems to account for the peculiarity of croupous inflammation, and I do not think that it is due to any specific cause. Indeed, direct experiment has shown that severe irritants induce the formation of false membrane on mucous surfaces; and we must rest content with the conclusion that in young animals growth is rapid, and that the new formation is so rapid in growth, and so plastic in consistence, as to remain more or less firmly adherent to the structure from which it is developed.

The causes, as already indicated, are damp and cold, particularly exposure to heavy dews at night.

Symptoms.—These generally commence with a hoarse cough, discharge of frothy saliva from the mouth, and of mucus from the nose; the animal is unthrifty, has some difficulty in swallowing; sometimes swellings appear in the parotid and submaxillary regions, succeeded by difficulty in breathing, the inspiratory act being accompanied by a crowing noise, and by spasm of the laryngeal muscles, causing violent paroxysms. In other cases the spasmodic affection of the larynx and difficult breathing may occur without any premonitory warning. The pulse, hard and quick at the commencement, becomes feeble and indistinct as the disease advances, the fits of coughing more and more troublesome and violent; paroxysms constantly occur, particularly if the animal be subjected to any sudden excitement. In the course of two or three days flakes of false membrane are coughed up; the expectoration becomes more profuse; the false membrane, which never becomes organized or vascular,
is loosened and detached by a fluid poured from the mucous follicles, until it is finally separated and cast out; and if the case progresses favourably it is not again formed, the suppurative process terminating the inflammatory action.

If the stethoscope be applied to the larynx and trachea, a peculiar trembling may be detected in places where false membrane exists.

Treatment.—When the symptoms are very alarming, the breathing difficult, and the noise loud, tracheotomy should be immediately performed; indeed it is essential that air be admitted early in every severe case, for should the operation be delayed, the blood becomes so over-loaded with carbon and effete materials, that the animal succumbs to a condition of blood poisoning.

The head is to be steamed for several hours consecutively, and the hot water used for that purpose may contain carbolic acid or iodine. Nitrate of silver in solution may be directly applied to the diseased mucous membrane, as directed in a former page. The solution commonly in use contains half a drachm to the ounce of distilled water.

The medicinal treatment will greatly depend upon the condition of the animal, but little good need be expected from any very heroic remedies. In the early stages the nitrate or chlorate of potash are to be given in small doses, or the hyposulphite of soda in the animal’s drinking water. If there be much prostration, spirits of nitrous ether, with camphor, may be prescribed, and in all cases a gentle oleaginous purge may be ordered if the bowels are costive. It must not be forgotten that the patient must be kept in a warm, dry shed, and have the body clothed if the weather be cold.

DIPHTHERIA:

Diphtheria may be described as a specific blood disease, associated with sore throat of great severity, attended with extreme prostration, and characterised by exudation of false membrane upon and pulpification of the mucous membrane of the throat and sometimes that of the nose.

In the Veterinary Journal for August 1875, Mr. W. Robertson, Kelso, reports some facts in connection with the occurrence of diphtheria in dogs and horses and places on record the causes,
spread, and subsidences in two particular outbreaks—one amongst horses, the other amongst dogs.

Mr. Robertson restricts the term "diphtheria" to "that specific sore throat ordinarily regarded as contagious, accompanied with much systemic disturbance, and tending to laryngeal croup."

In both the outbreaks the fatality was great, all the horses—five in number—dying; in the case of the dogs, there were three or four recoveries from between thirty and forty seizures.

As seen in the horses the seizure was in every instance sudden; the animals—farm horses in good working condition, of different ages—apparently in the enjoyment of the fullest amount of health and vigour one day, were on the following found unaccountably ill; two, indeed, were only noticed unwell in the evening, having worked all day, and fed with their usual zest, both in the morning and at mid-day. Attention was first directed to the animals from their inability or disinclination to drink when offered water; some pushed their noses into the trough or pail, and seemed attempting to swallow, but at once desisted, or the water returned by the nose. The breathing was at the same time noticed to be rather faster than natural, and the nose slightly pushed forward; occasional muscular tremors at this time showed themselves, and the animals were rather restless or uneasy. There was little or no cough, and when it did exist, it seemed merely to result from attempts made to swallow. The glands of the throat were slightly swollen from the first, but certainly did not increase much during the period the animals lived. The temperature rose rapidly, and continued high until shortly before death; while the pulse was accelerated about one-half, but was considerably less in volume and force.

In one case there were well-marked symptoms of abdominal pain from the outset of the disease, with no abdominal organic lesion observable after death to account for these. In this instance there was also very noisy breathing; this, however, was accounted for at the post mortem examination, which showed more extensive involvement of the larynx and trachea than any of the others. None of these animals lived over the fifth day, and two of them died within forty-eight hours.

I have never witnessed a disease similar to that described by Mr. Robertson in the horse; but during the winter 1878-91 I had the opportunity of seeing several dogs, the property of various
owners, that had this fatal form of sore throat, and which presented signs very nearly approaching those of diphtheria as described by physicians.

The symptoms were those of great prostration and languor; flow of tears from the eyes; a very sunken and pinched appearance of the face; the power of swallowing completely lost; inability to close the mouth, which in all cases was persistently open, the muscles of mastication, as well as those of deglutition, having lost their function either from paralysis or inflammation. Indeed, the first symptom observed was a dropping of the lower jaw, and on this account it was supposed by the owners the disease was dumb madness; a more or less copious discharge of a viscid ropy saliva from the mouth, dirty yellowish-red tongue, the neck stretched and rigid, the glands slightly swollen, edematous, and painful to the touch. Diarrhoea was present in all, and the posterior extremities were paralyzed.

The mucous membrane of the mouth and fauces was of a dark red colour, swollen, tense, and glistening from extraneous infiltration, but no ulcers were observable.

Three of the dogs died in from twenty-four to forty hours after they were first observed, but the fourth, a staghound, lived for four days, the symptoms in it having been much more gradually developed. In none of the dogs were convulsions or coma present; they all remained conscious to the last, evidently dying from diarrhoea and exhaustion.

No history could be obtained with any of the dogs. One was a lady's pet dog, and was daintily fed; another was a brewer's yard dog, always on the chain; so it was impossible, in these two cases at least, that the disease could have been induced by any tainted—infected—food, even if diphtheria had prevailed amongst the inhabitants of Edinburgh. Such, however, was not the case, diphtheria being entirely absent at that time.

The disease did not seem contagious or infectious, there being several dogs at the College at the time; some of these, owned by students, being confined in the boxes in which the diseased ones had died for the purpose of testing its contagiousness. One dog was inoculated, the results being negative.

Mr. Robertson traces the outbreaks which he witnessed to unsatisfactory sanitary conditions of the stable and kennels. These being drained and better ventilated the disease disappeared.
Post mortem appearances.—The post mortem appearances in four different cases examined at the College in 1879 were pretty much alike. A frothy mucus escaped from the nose and mouth, and the joints remained quite flaccid for three or four days.

On cutting through the skin, the larger veins were found to be engorged with extremely black fluid blood; and on prickling an artery, blood of the same colour and consistency exuded from it. The mucous membrane of the mouth, and all other mucous cavities, was very much congested, and covered by a frothy mucus; that of the faucæ and tonsilar cavities being extremely so in two cases, having commenced to undergo granular degeneration; in a third, a false membrane had formed over the glottis.

All the cavities of the heart were filled with black fluid blood, and only here was there any appearance of its coagulating, and the pericardial sac contained a quantity of fluid.

The surface of the lungs looked unnaturally red, with here and there small dark spots; and on cutting into its tissue, the same dark fluid blood exuded from it.

The stomachs in two cases were filled with straw, stones, and other rubbish; but in the other two no such materials were found there.

The kidneys were also engorged with black blood.

Some interesting experiments are published in the Veterinary Journal for August 1875 as to the transmissibility of diphtheria, which the reader may profitably consult.

Treatment.—The treatment indicated by the symptoms is that calculated to destroy a virus, and for this purpose antiseptics, such as carbolic acid, might be worthy of trial. If the power of swallowing be completely lost, subcutaneous injections might be tried, and the throat repeatedly dressed with it, or a solution of permanganate of potash.
CHAPTER XLIX.

SPORADIC DISEASES—continued.

(III.)—LOCAL DISEASES—continued.

(I.) DISEASES OF THE RESPIRATORY ORGANS—continued.

INFLAMMATION OF THE RESPIRATORY ORGANS—BRONCHITIS.

Division.—This disease may, according to its seat, be arranged under four heads, namely, "tracheo-bronchitis," where the lower part of the trachea and larger tubes are the main seat of the inflammation; "bronchitis proper," where the medium-sized bronchi are the chief seats of the disease; "capillary bronchitis," where the smaller bronchi are chiefly implicated; and catarhal, lobular, or broncho-pneumonia, where the smallest bronchi and alveolar walls are involved in the inflammatory process. For simplicity of description I shall retain the generic term bronchitis, dividing it into acute and chronic.

The character of the inflammation, whatever part of the respiratory tract may be affected, is what is understood as catarhal—that is, an inflammation in which, instead of an exudation rich in fibrin, there is a fluid secretion containing a large quantity of mucus and cellular elements. In this particular it differs most essentially from inflammation of the lungs, originating in the parenchyma and from pleuro-pneumonia, in which the pleural surface as well as the lung structure is involved. The exudate in these is termed "croupous" or fibrinous.

Causes.—Bronchitis, wherever its seat, is generally due to exposure to cold; it may supervene on an attack of ordinary catarrh, particularly if the animal be neglected, exposed to wet and cold, or kept in ill-ventilated stables. It may also arise without any premonitory catarhal symptoms in both horses and cattle during voyages by sea, particularly if the weather be rough and
stormy, and the animals battened down. During 1877 the author had the opportunity of seeing bronchitis in its purest form, and which proved fatal to many, amongst foreign horses imported at Leith. An instructive fact in connection with these cases was that it appeared only after rough and stormy passages; when the weather was fine no cases were observed.

Amongst cattle shipped to this country from America during the earlier and spring months of 1879 bronchitis was observed almost identical with that seen amongst the foreign horses already alluded to; as the season advanced, and the weather became warm and less stormy, the disease disappeared.

Bronchitis, like laryngitis, may be caused by the inhalation of irritant matters, and by the accidental entrance of foreign materials, as medicines or food, into the bronchial tubes. Inflammation of the bronchial tubes arising from the latter cause usually occurs in horned cattle, often as a sequel to parturient apoplexy, in which affection the power of deglutition is in a great measure lost, and where the sensibility of the glottis is, during the comatose stage, greatly diminished or entirely absent. In such cases fluid medicines incautiously administered enter the trachea and bronchi, and these may cause immediate death by suffocation, or if not immediately fatal, induce a severe and perhaps fatal inflammation.

Again, during the state of coma, semi-fluid ingesta are apt to flow into the mouth through the flaccid oesophagus, particularly if the cow lies with its head and anterior extremities lower than the posterior ones. In parturient fever there is also very often during the earlier stages some extent of antiperistaltic action of the oesophagus, with eructations of gases from the rumen; along with such gases semi-fluid ingesta gain entrance into the fauces, and owing to the paralyzed state of the glottis fall into the larynx and trachea.

Catarrh or bronchitis, from other than mechanical causes, may, particularly in cattle, if the accompanying cough be long and powerful, cause some degree of vomiting. The food thus vomited, or in other words coughed up, sometimes gains entrance into the trachea, and causes a fatal issue.

Along with Mr. Borthwick, Kirkliston, I saw cases of this kind in a herd of Irish cattle brought to Scotland, and which were suffering from bronchitis and gastric irritation from neglect and exposure.
Four of the herd became much worse than the rest; one died, and the other three were slaughtered. In all of them the bronchial tubes were filled with ingesta, ejected into the fauces during violent fits of coughing. Again, in several specimens of the lungs of American cattle slaughtered at Liverpool, supposed to be affected with pleuro-pneumonia, food was found in the bronchi. Is it not possible that during a rough voyage cattle may suffer to some extent from sea-sickness, and even vomition, and that the vomited matters may gain access into the trachea and bronchi? In others of the condemned American cattle the irritation was associated with the presence of filaria in the bronchi. Both the ingesta and the parasites were present only in a minority of the diseased lungs examined, and could therefore be only looked upon as accidental concomitants.

Food sometimes gains access into the trachea in the course of dissolution, or even after death, particularly if the rumen be rather full of moist food; it will then be found in the greatest abundance in the trachea and larger bronchi, whereas in those instances in which it has been in the tubes for some time before death, the food will often have disappeared from the larger into the smaller tubes and air cells.

I have witnessed one case of fatal bronchitis in the horse, due to the entrance of vomited ingesta into the bronchi. Some days prior to its death fifteen minims of Fleming's tincture of aconite had been administered; this brought on attempts at vomition and great distress. The animal's respiration continued very highly accelerated after the effects of the aconite had passed off, and continued until the animal died. A post mortem examination revealed the fact that vomition had occurred, and that the small quantity of food thus expelled had entered the larynx, and gained access to the bronchi.

**Acute Bronchitis.**

*Symptoms.*—Bronchitis consists of congestion of the bronchial tissues, associated at first with dryness, narrowing, and rigidity, and subsequently moisture, dilatation, and relaxation of the tubes.

Owing to these changes, the vibrating sounds caused by the passage of air through the inflamed bronchi undergo variations, which indicate pretty clearly the dry or moist condition of the parts, or, as some term it, the dry or moist catarrh.
As the symptoms are developed, the cough becomes hoarse, ringing, loud, and paroxysmal; the respirations are in some instances greatly accelerated, indeed out of all proportion to the pulse. For example, the pulse may be seventy or eighty per minute, and the respirations as numerous, or even more so: this indicates bronchitis affecting the smaller tubes and alveolar walls—catarrhal pneumonia—collapse of a more or less extensive area of lung structure, or even occlusion of non-inflamed bronchi and air vesicles by the gravitation into them of the catarrhal fluid, as shown in the woodcut.

Fig. 28.—Small bronchus in acute bronchitis, occluded by a plug of catarrhal secretion.—3:50 diam. a, Catarrhal plug; b, Epithelium lining bronchus; c, Surrounding adventitious coat infiltrated with cells.—(From American or condemned at Liverpool for pleuro-pneumonia.)

Bronchitis of the larger tubes is naturally less dangerous than the other two, and only proves fatal by inducing the two above-mentioned conditions, namely, collapse and occlusion of a more or less extensive breathing surface.

1 This woodcut has already appeared in The Practitioner for July 1879 (fig. 25). "The accompanying figure shows how the occlusion may occur. It will be noticed that the plug of catarrhal secretion has apparently not been formed at this part, but must have been inspired, as the epithelium of the bronchus is still complete." (Dr. HAMILTON in Practitioner.)
Amongst the foreign horses above alluded to, it was noticed, where the discharge of muco-purulent matter was most profuse, although some of the animals seemed to recover from the febrile disturbance and accelerated breathing of the acute stage, that they succumbed in from fourteen to thirty days afterwards from gangrene of the collapsed lungs, or putrefaction of the fluid incarcerated in the bronchi and air cells; both of these conditions being expressed by fetor of the breath, exhaustive diarrhoea, metastatic inflammations of the articulations and feet, complete loss of appetite, rapid emaciation, fluttering pulse; at first great elevation of temperature—106° F. or more; partial sweats upon the body, gasping respiration, some abdominal pain, and other signs of general septicemia.

In no case of pure bronchitis is the breathing painful, but short and quick, the thoracic as well as the abdominal muscles being brought into full play; this distinguishes it from the breathing characteristic of pleurisy, in which the ribs are more or less fixed and the respirations abdominal. In ordinary cases of bronchitis the animal is dull, listless, sometimes semi-comatose; hangs its head; is generally thirsty; ropy saliva fills the mouth, which is hot and moist. The visible mucous membranes are injected, and present a varying degree of lividity, due to non-oxidation of the blood. The animal stands in a corner or moves listlessly about. If in a box, and the door be open, it stands with its head to the open air, from which it evidently obtains relief. The bowels are generally somewhat constipated, the feces covered with mucus, but they easily respond to purgatives, showing that the alimentary mucous membrane participates in the irritation. The urine is high-coloured, scanty, and if examined will be found to contain urea, mucus, and colouring matter in excess, and the chlorides in diminished quantities.

As already stated, bronchitis of the larger tubes is not ordinarily a fatal disease, but when affecting the smaller bronchi and alveoli, particularly if associated with a profuse discharge of a yellowish coloured, more or less tenacious fluid, which occludes the smaller bronchi and air cells, it is the most fatal chest disease that the author is acquainted with. This tendency to gravitation of the catarrhal fluid is explained by the fact that the columnar and ciliated epithelium are shed in the earlier stage of the attack, and take no part whatever in the after changes which ensue: “It is
never seen again till the signs of acute inflammation, such as
distension of the vessels and edema of the basement membrane,
have passed off. Subsequently it is gradually reproduced."—
(Dr. Hamilton.)

The muco-purulent material thus incarcerated is driven or
impacted by the ramrod-like action of the inspired air into
the periphery of the smaller tubes and vesicles, and there con-
stitutes those masses which may undergo putrefaction in the
horse, causing septicæmia, as already explained, and caseous
masses, giving rise to tubercle in the ox.

The physical signs of bronchitis are as follows:—Percussion
returns a more or less resonant sound, but auscultation will enable
the practitioner to detect the nature and extent of the bronchial
inflammation. Rhonchus, confined to the upper and middle
third of the chest, with true respiratory murmur over the lower
part, will indicate inflammation of the larger and middle
sized bronchial tubes, and a condition of comparatively little
danger. Sibilus, heard at the lower parts, indicates a condition
of much greater danger, and that the disease involves the
smaller tubes and air vesicles. Inspiration is generally short-
ened, expiration prolonged, and more distinctly accompanied by
the abnormal sounds. These sounds are succeeded at a later
stage by moist bubbles, rattles, or rales—mucous rales. At first
the discharge expelled by coughing is thick, tenacious, and gelat-
inous, or watery and scant. The lower animals do not, however,
expectorate in the true sense of the word; some discharge issues
from the nose, but the greater part of what is coughed up falls
into the fauces, and is swallowed. As the disease advances,
however, a profuse discharge issues from the nostrils, and the
inflammation gradually subsides. The cough becomes less
hoarse, more vigorous, and even more frequent than at first; but
it gradually disappears, the discharge becomes again thinner,
clearer, and eventually ceases.

In some instances all sounds disappear from a certain part of
the lungs. This is due to occlusion of the tubes and vesicles
by the catarrhal secretion, or to more or less collapse of the
vesicular tissue, dependent on obstruction to the passage of air
during inspiration by glutinous or inspissated mucus. This
collapse is often confined to individual lobules, which are thus
condensed, heavy, indurated, and of a dark colour, and may
ultimately become hepatized, atrophied, or even emphysematous.
PATHOLOGY AND MORBID ANATOMY.

Inflammation of the bronchial tubes, like that affecting other mucous membranes, is attended with changes in their epithelium, the secretion of the glands, and in the surrounding tissues.

It is rare to meet with a fatal case of bronchitis during its earlier stages, and but for the accidental slaughter in Liverpool of the American cattle already referred to, it would have been difficult to have given the details of the morbid anatomy.

The appearance of the lung in the earlier stage of bronchitis, with collapse, that is to say, when it is observed prior to the commencement of secondary changes or phenomena, is as follows:—There are patches over its surface that have fallen below the level of surrounding parts; sometimes these depressions measure an eighth of an inch in depth; they are of a bluish-purple colour, and variable in size. The parts around them are of a light pink hue, and are either healthy or in a more or less emphysematous condition.

![Image](image_url)

**Fig. 27.**—Portion of lung from American ox slaughtered at Liverpool, and showing bronchitis in the very earliest stages (a a, collapsed lobules) from obstruction of tubes. The elevations (b b, non-collapsed lobules) are slightly emphysematous.

The depressions consist of certain lobules in a state of collapse arising from occlusion of their bronchial tubes by pus or other material. The collapsed portions are bluish-purple in colour; non-crepitant, and depressed, resembling fœtal lungs, sinking slowly in water.

Collapse of the lung tissue—atelectasis—induces more or less
congestion and subsequent inflammation; consequently it is found that broncho-pneumonia often succeeds bronchitis, due to the absence of the expansion and contraction of the air vesicles which normally aid the pulmonary circulation, and to arrestment of the blood-flow owing to imperfect respiration. This congestion is soon succeeded by effusion of serum, and the bluish-purple collapsed portions become darker in colour and less resistant in consistence. They, however, retain some degree of elasticity, for, if not too rudely pulled out, they do not tear as in pleuro-pneumonia; if cut into and exposed to the atmosphere for a few minutes, the bluish-purple colour becomes bright scarlet. It is important to bear in mind that the pneumatic process which supervenes in bronchitis is principally confined to those portions of the lungs in which collapse has taken place. Sometimes the collapse is isolated, invading but small portions of the lungs; this condition is not rarely witnessed in parasitic bronchial disease. These limited collapsed portions vary in size, are rather wedge-shaped, and have their apices towards the obstructed bronchus. The lung tissue surrounding them may be more or less congested, or it may be emphysematous, but no juice is exuded from them when cut into, as in acute pleuro-pneumonia.

Professor Gairdner was, I believe, the first to show that condensation of the vesicular substance occurs as a result of mucous or other obstruction in the air-tubes leading to the condensed portion. It is at first sight difficult to understand how incomplete obstructions of the bronchi—and these obtain much more frequently than absolutely complete occlusion—cause collapse. One would suppose that some quantity of air would gain access into the vesicles, but such is apparently not the case; and it seems that the air gradually finds its way out by the edges of the obstructing substance. The expiratory force, so long as there is air in the vesicles, constantly tends to dislodge the obstructing body by pushing it towards the wider (proximal) end of the tube, whilst the inspiratory drives it inwards towards the narrower tubes, which it effectually occludes. The entrance of air is thus more or less effectually opposed, and its exit permitted, so that ultimately the vesicles beyond become completely emptied; in fact the plug acts as a valve, allowing the air to pass in one direction, but opposing its passage in the other. Where the
obstruction is complete from the commencement, the air is absorbed.

It had been supposed by Laennec that the emphysema, or, more correctly, the over-distension with air of the parts surrounding the collapsed lobules, was due to what he thought a fact, that the act of inspiration was more powerful than that of expiration, so that though air could be drawn through the obstruction, it could not be breathed out. In consequence, it accumulated in the ultimate pulmonary vesicles, became expanded by heat, and so acted mechanically as a dilator. Dr. Gairdner, however, pointed out that expiration is a much more powerful act than inspiration, and that there is never any difficulty in causing expulsion of air, provided always there be no obstruction in the tubes. Emphysema, then, does not occur in the vesicles connected with obstructed tubes, but in those which are adjacent. When the lungs are free from disease the column of air presses equally in all the tubes and vesicles; but when one portion connected with any obstruction is collapsed, then the adjacent parts are over expanded, so as to occupy the space previously filled by the former.

At a later stage the contents of the obstructed bronchi are pushed by the weight of the descending or inspired atmosphere into the most minute bronchi, alveoli, and air vesicles, always from the centre towards the periphery, and appear as minute white points beneath the pleural surface. They are well shown in the figure.

![Image](Image)

**Fig. 28.—Pleural aspect of pulmonary lobe from American ox slaughtered at Liverpool; alveoli filled with mace-parulent matter; pleural surface intact.** The microscopic examination revealed broncho-pneumonia in some of the alveoli (see fig. 28); whilst others showed no traces of inflammation (see fig. 29), but were merely filled with the inhaled bronchial secretions.
On cutting into the lungs, it will be found that the large and small tubes, and sometimes the trachea, contain an amount of fluid. This condition, as well as the collapse, is limited in the majority of instances to the small or anterior lobes of the lungs, and rarely, except by extension, affects the large lobes, not only in ordinary but in mechanical bronchitis. This fact is of importance, as pleuro-pneumonia contagiosa, with which the disease under consideration has been confounded, generally commences in the larger lobes, either in their centres or towards their posterior edges.

The fluid contained in the tubes is thick, and has a yellow colour; in the trachea it is more or less frothy; and is abundant in the smaller bronchi, as shown in the figure.

![Figure 23](image)

*Fig. 23.—Section of portion of lung; the external aspect is shown in fig. 22. The larger (a) and smaller bronchi and air vesicles (b) filled with purulent matter.*

If the lungs in this condition be squeezed, little pellets of yellow matter are pressed out; sometimes these pellets are too small to be seen by the naked eye, and require the aid of a magnifying glass. If the bronchitis be associated with catarrhal pneumonia, elevated patches will be apparent on the cut surface, having a greyish-red colour. They are soft to the touch, and if squeezed, the same muco-purulent matter exudes from them, or from a small bronchus which may happen to communicate with the particular group of vesicles implicated.

Dr. Hamilton, in his series of papers on bronchitis published in the *Practitioner* for 1879, states it is a matter of difficulty in man to get at the first change which ensues in the bronchi in acute catarrh. He has, however, been able to verify his observations by an examination along with myself of the lungs of American cattle slaughtered in the earlier stages of bronchitis;
in fact before any external signs of disease were manifested. He says—"On careful comparison, however, of many cases, we feel assured that the first deviation visible is a relaxation and distension of the abundant plexus of blood-vessels ramifying in the inner fibrous coat, immediately beneath the basement membrane—that is to say, of the branches of the bronchial artery. They become engorged with blood, so that on transverse section they appear like little cavities distended with blood corpuscles. In a few hours afterwards the basement membrane\(^1\) becomes much more apparent than it usually is, and at the same time more clear and homogeneous, while the surface is thrown into many folds. These changes in the basement membrane are apparently due to its becoming oedematous, serous fluid being infiltrated into it from the underlying plexus of distended vessels; and we shall see that, as the acute irritation continues, this oedematous state of the basement membrane becomes more and more a well-marked feature. The next change, so far as we have been able to calculate, occurs in from twenty to thirty

---

1 The basement membrane is not so apparent in the lower animals as in man.
hours after the primary distension of the vessels, and consists in
the loosening and desquamation of the columnar epithelium at
the foci of greatest congestion.

"The columnar epithelium is thus shed at a very early stage
of the attack, and takes no part whatever in the after changes
which ensue. It is never seen again until the other signs of
acute inflammation, such as the distension of the vessels, and
œdema of the basement membrane, have passed off. Subse-
quently we shall see that it is gradually reproduced. The
cause of this desquamation of the columnar epithelium seems to
be the œdema of the basement membrane loosening its under-
lying attachments, very much in the same way as the vesicles
which form in an acute inflammatory affection of the skin loosen
the attachments of the superficial layer of epidermis. The
removal of this protective covering from the mucous membrane
naturally leaves the latter in an exposed condition, and no
doubt the feeling of rawness experienced in acute catarrh of
the bronchi is due to the cold air acting upon an over-stimulated
and exposed mucous membrane. And, further, it can easily be
understood that, where this desquamation takes place to an
inordinately great extent, the loss of the ciliary action of the
columnar cells will seriously interfere with expectoration, and
tend to cause the catarrhal products to gravitate downwards
towards the smaller bronchi and air vesicles. This description
essentially coincides with what Socoloff found experimentally in
animals (Virchow's Archiv, vol. Ixxxii, p. 611), in which he in-
duced an artificial bronchitis by the injection of irritants, such as
potassic bichromate, into the air passages. He states that one
of the first changes which ensued was the desquamation of the
columnar cells, and that they took no part in the catarrhal
inflammatory process." This early shedding of the columnar
cells, and their non-reproduction until after the subsidence of the
inflammatory process, is a fact of real importance, as it goes a long
way to explain the occurrence of those caseous tumours which
give rise to tubercle, and are so often confounded with that growth.

The pneumatic process, which may supervene either by ex-
tension of the inflammatory process from the tubes to the alveoli,
or the irritation of inhaled inflammatory products subsequent to
collapse, is, in the earlier stage, commonly limited to scattered
groups of air vesicles, hence the term lobular which is applied
BRONCHITIS.

It causes the portions affected to appear as scattered, ill-defined nodules of consolidation, irregular in size, and passing insensibly into the surrounding tissue, which is variously altered by collapse, emphysema, and congestion. These nodules are of a reddish-grey colour, faintly granular or smooth, slightly elevated, and soft in consistence. As they increase in size they may become confluent; and in a more advanced stage they become paler, drier, firmer, and to some extent resemble ordinary grey hepatization.

Microscopically examined, they are seen to consist of cellular elements accumulated in the alveoli.

The disease may, as already remarked, terminate fatally by the absorption of the putrescent catarrhal products, by gangrene of the collapsed lungs, or by sudden effusion of fluid into the bronchi, constituting what is termed suffocative catarrh. If a fatal termination does not ensue, the contents of the alveoli undergo degeneration, and are gradually removed, by discharge, or by absorption; or by coalescence form caseous masses, which may become encapsulated, undergo the calcareous change, and thus become innocuous; or may induce a diathesis, leading to the actual development of tubercle in the ox, and to symptoms.
accumulation of catarrhal products, epithelial and other cells, within the pulmonary alveoli; cellular infiltration and thickening of the walls of the alveoli and bronchi; increase in the interlobular connective tissue, with, in some instances, the occurrence of fibrinous masses, intermixed with leucocytes in the alveoli, as demonstrated by Zenker of Dresden, but without—except very rarely in the horse—the occurrence of tubercular tumours (grapes) in the serous membranes and parenchyma of organs.

In all cases of bronchitis the bronchial glands undergo some change. In the earlier stages they are increased in size, contain the products of the bronchitis conveyed by the lymph tract; become more or less friable in consistence; and in more advanced bronchial inflammation distended with catarrhal elements; both glands and contents undergoing the caseous metamorphosis, the products of which may either liquefy or become infiltrated with calcareous matter.

**TREATMENT.**

Venesection is to be avoided; indeed bronchitis is characterised by depression and debility from its earliest stages. In the very commencement of the disease the irritation is generally modified by a moderate dose of opium. In the horse, ox, and sheep remedies termed expectorants are quite useless, having no effect. In the dog, however, they are said to act. They are antimonial wine, ippecacuanha, hyoscyamus, &c.; but I do not think that they are of much service, and are not to be compared to chloral hydrate in from two to four grain doses. The great principle of treatment, however, in all animals after the very earliest stage of the disease has passed off—when, and then only, it may be possible to cut short the attack by a full dose of opium—is to assist in promoting the natural course and termination of the inflammation. It has already been pointed out that in the earlier stages the bronchi are dry, and that subsequently they become moist; and as the moist stage becomes, as it were, matured, the irritation disappears. Such, then, is the natural course, and the practitioner is to assist in promoting this by causing the animal to inhale steam, medicated or simple, the medicated steam being made by adding camphor, creosote, or carbolic acid to the hot water. When the discharge is profuse,
indicating the involvement of a large area of tubes, and a condition of real danger, the inhalation of steam is of the utmost importance, as such inhalation modifies the viscosity of the catarrhal fluid, and facilitates its discharge from the bronchi. And in order to prevent as much as possible the putrefaction of the catarrhal product, such steam should be medicated with carbolic acid. In addition to this the sides are to be bathed with hot water, and rubbed over with oil or a weak liniment to keep off the sensation of cold. If the bowels are costive, enemas are to be administered, but on no account are aloetic purgatives to be given; for obstinate constipation—a very rare complication—a moderate dose of oil may be given. It is far better, however, to keep the alimentary canal in proper order by enticing the animal to eat laxative food, such as linseed mashes, carrots, or grass, if in season. Some practitioners recommend that sulphate of magnesia be given in four-ounce doses daily in the horse’s water until the bowels respond. For my own part I have found that horses generally refuse to drink such water, although they may suffer much from thirst; and I generally content myself with ordering half-ounce doses of nitrate of potash twice daily in the water or mash. Good nursing, warm clothing, pure air, and a good stable or loose box, are essentials which are not to be forgotten.

In the course of bronchitis, it will frequently be observed that symptoms simulating those of diabetes insipidus become developed; the animal becomes very thirsty and urinates profusely. These need not cause any alarm; they are due to the absorption and elimination of effete materials and various salts—chloride of sodium particularly—which have been retained, probably in the inflamed part, during the active stage of the disease. If the patient be freely supplied with water, and enticed to partake of good food, the diabetic symptoms pass off, and the animal will speedily become convalescent.

Should debility remain, with cough and irritation, hyoscyamus and tonics are to be administered; and if the case threatens to become chronic, a blister may be applied to the throat and breast, and the iodide of potassium prescribed.

Chronic bronchitis in the horse may cause what is termed thick wind, chronic cough, and eventually emphysema from rupture of the rigid and altered air vesicles and small bronchi.
CHRONIC BRONCHITIS,

As indicated by a loud, metallic cough, emaciation and debility, is not an infrequent disease, particularly in horned cattle, and is due to thickening of the bronchial and alveolar walls, and to caseous masses. It is best treated by hydrocyanic acid, in doses varying from \( \frac{1}{4} \) to \( 1 \) dr., Scheele's strength, in combination with nitrate of potash and bicarbonate of soda, twice per day, a strong blister to the breast, and careful housing and nursing. A morbid change, termed bronchiectasis or dilatation of the bronchial tubes, arising from a chronic interstitial pneumonia, induced by acute croupous pneumonia, broncho-pneumonia, pleurisy, and the inhalation of solid irritating particles, is witnessed in the human being. It is characterised by thickening of the interlobular septa and alveolar walls; and when the fibrosis is extensive, the lung is diminished in size, the tissue is smooth, dense, being in parts almost cartilaginous in consistence, and irregularly mottled with black pigment. The alveolar structure of the lung is in most parts destroyed, and on section the dilated bronchi are seen as numerous large openings scattered over its surface. The dilated bronchi frequently become the seat of secondary inflammatory processes, which may lead to ulceration, and ultimately to extensive excavations of the indurated tissue; but there is a complete absence of caseous changes. The pleura is almost invariably thickened and adherent, the new formation in the earlier stages usually contains new blood-vessels, but later the tissue contracts, and the vessels become destroyed; the contraction of the false membrane may also induce deformity of the chest, and twist the neck to one side. I have seen a case similar to the above description in a dog in which the lungs contained quantities of sand. This dog had been several years in Africa hunting with its master. Before death it was observed that the right side of the chest was depressed, and this was found to be due to caseification and contraction of the adherent lung and connecting new formation.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(I.) DISEASES OF THE RESPIRATORY ORGANS—continued.

CHRONIC EMPHYSEMA OF THE LUNGS.

Chronic Emphysema of the lungs is of two kinds, namely—(1.) Vesicular, due to enlargement and dilatation of the air cells, with gradual effacement of the blood-vessels distributed over their walls. There is anemia of the affected parts, a tendency to dilatation of the right cardiac ventricle, and a disposition to anasarca of the limbs. The dilated cells vary in size, and when very large it is probable that several vesicles are dilated into one cavity by rupture of the vesicular walls and partitions. These dilatations may be clearly seen through the pulmonary pleura, as they protrude from the surface of the lungs; they are pale, sometimes quite white, the tissue drier than natural. Vesicular emphysema is seen in chronic broken wind, and is due, as already explained, to degeneration of the bronchial tissues. It is, however, a result of bronchitis, and several theories are put forward to explain the origin of emphysema. Dr. Elliotson considers that a want of due expansion of the lungs is the most common cause. He says—"Whatever prevents any one part of the lungs from expanding when the thorax expands, whether it be a material obstruction of the bronchial ramifications or a compression of them, or whatever else, it will occasion those parts which remain dilatable to keep dilated in a corresponding increased degree, in order to fill up the vacuum which the expansion of the chest occasions. When we inspire we dilate the chest, and the air rushes down the trachea, and the lungs follow
the dilated portions. If there be any part of the lung that will not dilate, then other parts are over-dilated to fill up the vacuum, and in that way those parts which we distend are over-distended, in order to compensate for the want of distension in other parts; and when once over-distended they are often unable to recover themselves, just as is the case in other parts of the body—the urinary bladder for example. I presume it is on this account that dilatation of the air cells is so common in persons labouring under chronic bronchitis, especially where the membrane is most thickened, and where the secretion, if there be any, is tough and adherent, so as to produce obstruction."—(Practise of Medicine.) And, as already explained, emphysema does not occur in the vesicles connected with obstructed tubes, but in the healthy ones which are adjacent. (See Bronchitis.)

2. Interlobular Emphysema, or accumulation of air or gases in the meshes of the connective lung tissue, may arise from rupture of the walls of the air vesicles. This result of rupture is, however, an uncommon occurrence, for generally, when the cells are ruptured, they break one into another, and form permanent enlargements, with rigid walls, by coalescence. Interlobular emphysema is, however, seen in various diseases, especially of horned cattle, and arises from the evolution of gases, which infiltrate and distend the pulmonary areolar tissue. It may be induced artificially by the injection of the bicarbonate of soda into the veins. It is also seen in an animal which has been destroyed by "blowing," i.e., by forcing air into the jugulars.

TREATMENT.

No permanent benefit can be expected from any treatment. Much relief may, however, be afforded by careful dieting, keeping the bowels regular, and when the paroxysms of dyspnoea are very great, by the administration of sulphuric ether, chloral hydrate, or the bromide of ammonium. A horse thick in the wind, or suffering from chronic cough, is an unsound animal.
CHAPTER LI.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(I.) DISEASES OF THE RESPIRATORY ORGANS—continued.

CONGESTION OF THE LUNGS—PULMONARY APOPLEXY—MECHANICAL ENGORGEMENT.

Apart from inflammation of the lungs, which will be described immediately, the lower animals, particularly the horse, are apt to suffer from congestion of the true pulmonary blood-vessels, i.e., the branches of the pulmonary artery. This congestive condition is not only seen during the progress of many diseases, such as laminitis, traumatic arthritis, enteritis, pneumonia, heart affections, and various prostrating epizootics; but often originates in the horse during severe exertion, more especially in the hunting-field when the animal is not "in condition," or is taxed beyond its strength. As a question of jurisprudence, the occurrence and results of congestive pneumonia, or, more correctly, pulmonary apoplexy, is a matter of some importance, for many instances have occurred, and will doubtless again occur, of horses dying from this affection within a few days after purchase, and the seller has been more than once mulcted in damages to the full value of the animal.

In order to bring a horse into "condition" for severe exertion, it is necessary that it be gradually trained. First of all, it is for a time walked for one or two hours daily, in order that the locomotor muscles be gradually brought into tone for stronger and severer work; then it is trotted, and afterwards galloped and sweated. Useless fat is thus removed, and the muscles of locomotion, as well as those of respiration, are brought into a condition and tone which enable them to perform the severest and fastest exertion; the tone and power of the heart are also
increased and elevated, whereby it is enabled to pump an increased supply of blood to all parts of the body, in order to maintain their strength and integrity during the time they are so greatly taxed. In fact, it may be said that the horse’s respiratory organs—wind—circulation, and muscular action, are elevated into a high state of functional perfection by careful training, and a horse in this condition will perform during a long run with the hounds or on the race-course, without danger to his health and life. But if a horse that is not thus trained—not in condition, no matter how good its health might be—is suddenly put to severe and prolonged exertion, when neither its muscular, pulmonary, nor circulatory systems are fit to undergo the fatigue consequent thereon, it will be seen that, first of all, the breathing becomes frequent and distressed; the heart beats tumultuously, but with little impulsive force; the voluntary muscles, consequent upon want of tone and exhaustion, obey the will imperfectly. It goes “all abroad,” as the horseman says. The breathing becomes more and more distressed, and at last it falls, and perhaps dies from actual suffocation, consequent upon the pulmonary vessels being overloaded with non-oxidized blood; and after death the lungs are found gorged with blood, black in colour, and prone to rapid decomposition, giving origin to the expression “black as your hat, and rotten as a pear,” and to the idea that the animal had suffered from some chronic disease. In giving an opinion on a case of this kind, the veterinarian must bear in mind that the blackness, tendency to putrefaction, or even deliquescent condition of the lung tissue, are results of acuteness of attack, and not of any previous disease; and it may always be accepted that mere engorgements and blackness, without the formation of an exudate, are positive evidence that the disease is not of long standing.

Another cause of congestion of the lungs is actual want of air in badly ventilated stables, the congestion here arising from the stop-cock action of the pulmonary capillaries already described—(see Death by Suffocation)—which contract, and prevent, as it were, as much as possible the passage of impure blood into the left side of the heart and systemic circulation. Pulmonary apoplexy is also termed hemorrhagic infarction, and, as explained by Dr. Yeo, is “universally admitted to depend on a local impediment to the circulation, such as an embolus impacted
in an artery. There being no arterial anastomosis in the lung, such a plug has a very marked effect. The embolus cuts off the normal supply of blood from the part, and the pressure in the arterial branches beyond the stoppage falls to zero. The blood, however, can still find its way through the capillaries into the branches at the distal side of the plug. The branches of the occluded artery are thus reduced to the condition of occluded veins, and as they have none but capillary connections, they may be said to form blind ends to the adjacent arteries. The blood then trickles into these arterial branches and fills them, but no outward flow can take place, therefore they become intensely engorged with stagnant blood. Under these circumstances, the inner coat of the vessel is deprived of its nutrition, for which the constant renewal of the blood is required. This starvation of the minute vessels renders them unfit for their function; they lose their power of retaining the blood, which escapes into the neighbouring textures, forming the dense black consolidation now known as hemorrhagic impaction."

SYMPTOMS.

The symptoms of pulmonary apoplexy are very distressing. The animal stands with outstretched legs, and seems to fight for breath; the nostrils will be seen opening and closing quickly, the flanks to heave rapidly; the eyes are blood-shot and wild, or sunken and dull; there is a tremor all over the body; the legs and ears are deathly cold, and cold sweats bathe the body; the pulse is small and indistinct ("the oppressed pulse of pneumonia" of the old writers), perhaps beating from 100 to 150 per minute in extreme cases; the heart's action tumultuous, but without strength.

In some cases there will be some discharge of frothy blood from the nose; in others hemoptysis is absent, and if the jugular or other vein is opened, the blood trickles from it, black, thick, and scanty. Death occurs by apnea.¹

¹ The term apnea is used by physiologists to indicate a condition of breathlessness induced by excess of oxygen (Handbook for the Physiological Laboratory, by Sanderson and others, page 318), and by pathologists that of suffocation or asphyxia.
TREATMENT.

In the first place, it is necessary to have the horse so placed that it can obtain as much pure air as possible. It is therefore to be tied with its head to the box or stable door, the body to be smartly rubbed, not knocked, with wisps of hay or straw, and afterwards warmly clothed. When the surface of the body and extremities are very cold, I have found it to be a good practice to place the feet in hot water and bathe the legs for several minutes, then rub them over with a stimulating emulsion, and bandage them in thick flannel as high as possible. If proper bandages cannot be obtained, hay or straw ropes are to be substituted. The medical treatment must be that which is calculated to equalize and balance the circulation, and for these purposes stimulants are to be recommended, such as the ethers, spirits, wine, or even ale when nothing else can be obtained. I have also found that the tincture of arnica, in one or two ounce doses, acts very satisfactorily; it seems to stimulate the cutaneous circulation, and on this account is well calculated to restore the equilibrium of the circulation. If the congestion does not give way to the above treatment, bleeding is to be resorted to, in order to relieve the pressure on the pulmonary vessels, and the engorgement of the great veins and right side of the heart; from four to six quarts of blood may be withdrawn with safety, but it is better not to repeat it. I am of opinion that it is a cruel practice, and one calculated to do harm, to apply mustard or other powerful irritant to the sides. Horses, when thus treated, begin to be excited in a few minutes after the irritant has been applied, paw, move about, lie down, and perhaps roll in pain; the breathing becomes more accelerated, and loss of strength rapidly follows. I hold it to be imperative that the veterinarian should enjoin perfect quietude and repose, and if anything is to be applied to the sides or breast, let it be warm water, in order to soothe and calm the distressed sufferer.

After the symptoms of congestion have passed away, it is not improbable but that they may be succeeded by those of inflammation of the lungs. Bearing in mind the probability of this sequel, the treatment of the animal for some days must be of the most careful description; the diet must be light, sparing, and easy of digestion; the water must be supplied abundantly,
and even in the earliest stage, if the animal be thirsty, water is
to be freely allowed; doses of nitrate of potash given in the
water or mash; the air of the stable must be abundant and pure
—but the horse is not to be exposed to draughts—and the body
kept warm by clothing.

POST MORTEM APPEARANCES.

The post mortem appearances are, congestion of the pulmonary
vessels, with rupture of some of them, and extravasation of blood
into the parenchyma, constituting pulmonary apoplexy, whilst
others are plugged by emboli. The lungs resemble the spleen,
and the term splenification has been applied to this condition.
When cut into, the lungs present a deep, dark, purple colour,
the vessels are filled with dark blood of a tarry consistence,
whilst here and there, interspersed throughout the lung
substance, darker points are seen, indicating where extra-
vasation has occurred. Although much heavier and more
condensed than natural, the lung tissue will generally float
in water; thus differing from the condition of hepatization,
which is present when death has occurred from pneumonia.
The right side of the heart and great veins are filled with blood
of a dark appearance and tarry consistence. The left side of
the heart also contains some quantity of blood of the same
appearance and consistence.

It may be stated that hypostatic congestion may occur post
mortem or during the death struggle. This always occurs in
the most depending part of the lungs, is to be distinguished by
its situation and the antecedent symptoms, the animals having
died from other diseases, and is not to be confounded with any
diseased condition of the lungs.
CHAPTER LII.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(I) DISEASES OF THE RESPIRATORY ORGANS—continued.

INFLAMMATION OF THE LUNGS—PNEUMONIA.

Synonyms and Varieties.—Peripneumonia; peripneumonia vera (as opposed to peripneumonia notha, or capillary bronchitis); febris pneumonica; acute pneumonia; chronic pneumonia; lobar pneumonia; interlobular pneumonia (an affection of the interlobular tissue); primary pneumonia, secondary pneumonia (signifying differences in origin); specific or glandorous pneumonia.

PATHOLOGY.

Congestion or engorgement of the lungs has been already described as a result of arrested pulmonary circulation arising from over-exertion, debility of the heart's action, embolism, or to any other circumstance preventing the due arterialization of the venous blood, and causing haemorrhage from or stasis in the terminal branches of the pulmonary artery.

Inflammation of the lungs is a disease in which all the textures of the pulmonary substances are more or less involved; and this distinction may be made between congestive and inflammatory pneumonia, that, in the first the lesion lies primarily in the pulmonary vessels, and, in the second, in tissues supplied by the branches of the nutrient vessels of the lungs, namely, the bronchial arteries, the pulmonary branches becoming subsequently involved, and having no inconsiderable share in
furnishing the exudative materials, which characterise the condition of hepatization or consolidation that occurs in pneumonia.

The various changes which occur in the course of pneumonia are—1st. Arterial injection, characterised by a brighter colour, and dryness of the pulmonary tissue, a condition indicated by harsh respiration and crepitating sounds. 2d. The arterial injection is succeeded by a condition of engorgement, congestion of the pulmonary vessels, and incipient oedema of the lung. The substance of the lung is engorged with blood and bloody serum; externally it is of a dark red colour, and crepitates but slightly under pressure; it also pits under the finger, and is more easily torn than healthy lung; is heavier than natural, inelastic; its cells are filled with liquid, mixed with air. On being cut a large quantity of bloody serosity escapes from the cut surface, which is frothy in the earlier stages from admixture with air. This, along with the commencing consolidation, proves that the effusion has been poured into the bronchial tubes and air vesicles as well as into the pulmonary tissue. During this stage the lung tissue will still float in water, although it is heavier and less crepitant than natural.

If a very thin section be made, and examined microscopically, the capillaries will be found filled with blood; the air vesicles enlarged and granular, with incipient division of their nuclei; and exudation corpuscles, mingled with red globules, which have escaped from the vessels and are seen in the alveoli.

3d. Red Hepatization.—If the inflammation continue, other changes occur in the lung substance. The lung is red externally and internally; is solid, sinks in water, and no longer crepitates under pressure; it, however, tears easily and breaks down under pressure; and on this account Andral objected to the term hepatization, and termed the second stage of pneumonia red softening—ramollissement rouge. The colour is less livid than in the earlier stage, being a dull reddish-brown, becoming brighter on exposure to the air. This reddish-brown colour is never very uniform, and in some animals diversity of colour is very marked: thus in the ox the inflamed lungs present such a variety of colour as to cause the term "marbled" to be applied to it. This is due to the very distinctly lobulated anatomical character of the ox’s lungs, and the consecutive nature of the lobar pneumonia. Dark red spots indicate the
earlier or second stage and the grey spots the third or later stage of the disease, which is called—

4th. **Grey Hepatization**, termed by Andral _ramollissement gris_ or grey softening. In the horse, perhaps the term grey softening may not be inappropriate, but in the ox solidification expresses the condition much more accurately. The cut surface of the part which has run on to this stage presents a grey tint, the redness of the preceding stage having passed away, and the granular character is less distinct. In the horse, dog &c. the tissue has very often lost its firmness, and has become soft and pulpy, and an abundant dirty-looking puriform material oozes from the cut surfaces. In the ox the grey portions are generally smooth, glistening, and firm. In some instances the smooth, glistening appearance is observed in the inflamed lungs of horses, but the firmness is rarely so great as in the lungs of oxen, in which the tissues of consolidated parts retain their marbled appearance, and acquire a resisting character, or are transformed into a more or less firm cheesy material. In some instances, however, the grey exudate, even in the ox, is broken down into a more or less pulpy material.

If a portion of hepatized lung be torn, and the torn surface examined with a magnifying glass, the tissue will appear to be composed of a crowd of small red granulations, lying close to each other, air vesicles clogged up, thickened, and made red by the inflammation. In the catarrhal form of pneumonia commonly seen in the horse, the exudative products are mostly accumulated in the interior of the air vesicles, but in the exudative form (croupous) seen in the ox, and in cases of pleuropneumonia in the horse, the exuded materials not only fill the air vesicles but the interstices of the pulmonary connective tissue.

Suppuration of the lung is a more advanced state of grey hepatization; the lung is softer, yellower, and more pulpy, but the condition is not materially distinct from the others, as pus cells are present in the advanced stages of pneumonia, and the distinction between softening, grey hepatization, and suppuration is more one of terms than of reality. Diffuse suppuration of the lungs is not rarely witnessed in newly calved cows; exposed to wet and cold, it runs a rapid course, terminating fatally in three or four days, the lungs being engorged with puriform materials. It is a
remarkable thing that suppuration of the lungs very rarely runs on to the formation of abscesses when the inflammation is not due to a specific cause, such as glanders or pyemia. I have certainly seen abscesses in the lungs of both oxen and horses, but the event is a very rare one, and Sir Thomas Watson endeavours to account for the rarity of pulmonary abscesses in a very ingenious manner. He says—"When I was speaking of inflammation in general, I pointed out to you the remarkable influence which the presence of air in contact with the inflamed part has in accelerating or determining the event of suppuration. In a recent cut through the skin the admission or the exclusion of the air to the cut surface will make all the difference between the adhesive and the suppurative inflammation; and so in other cases which I then mentioned, and will not now trouble you by repeating. Now it seems to me that the same principle obtains in inflammation of the lung. First, there is an effusion of serum and blood, then of lymph and blood; but the air, passing into the surrounding sounder tissue, and penetrating for a time even the inflamed portion itself, causes the suppurative process to supersede the adhesive; and so no wall of circumsallation is formed by the coagulable lymph, as is the case in areolar tissue when not accessible by the air."—(Watson’s Lectures, page 81.)

Gangrene is more generally a result of congestion than of inflammation of the lungs, but its occasional occurrence in pneumonia is indisputable. Sometimes it occupies a large portion of the lung, and is not circumscribed, sometimes it is more limited. The affected parts are dark, dirty olive or greenish-brown in colour; fetid in odour; moist, wet, and diffusent in consistence. The occurrence of mortification has been ascribed to thrombosis occurring in the branches of the pulmonary artery—(Huss, Carswell)—and to the destructive effect of the inflammatory process destroying the vitality of the tissue, or to an arrest of the circulation by the excessive accumulation of its products in the interior of the air cells.

Pneumonia may be double (bilateral) or single (unilateral), that is to say, it may affect one or both lungs; double pneumonia is, however, very uncommon. I have for many years carefully noted the site of pneumonia, and have found that the inflammation is much more commonly situated in the right than in the left lung, both in horses and in cattle, in epizootic, sporadic,
and contagious pneumonia; that, generally speaking, the inflammation commences in the inferior portions of the lungs; that it invades the tissue from below, upwards; that in all cases the bronchi are more or less involved in the inflammatory process; and that when the pneumonia is superficial, the pleura participates in the inflammatory process, losing its normal colour and translucence, becoming opaque, and covered with a layer of fibrinous material; that the exudation, whether it be into the parenchyma or on the surface, is fibrinous. When the disease originates deeply within the lung substance, the pleurisy may be and occasionally is absent.

When the pulmonary inflammation terminates in resolution, or a gradual return of the lung to its normal condition—and this termination is the most frequent one in ordinary pneumonia, provided the animal be properly treated—the exudates liquefy, undergo fatty degeneration and disintegration, and become so altered that they can be removed by absorption, and as the softened matters become absorbed, the circulation is gradually restored, and the lung slowly attains its normal character.

In glanderosus pneumonia, the exuded materials are transformed into an ichorous, infecting, puriform fluid, and in pleuro-pneumonia-bovina contagiosa they undergo a caseous change; the inflammatory process meanwhile continuing in other portions of the lungs until a large part of them becomes consolidated, impervious to air, and the animal dies from suffocation and anemia.

The various stages of pneumonia are manifested by certain sounds detectable by the ear when applied to the sides of the chest. In the first stage, and previous to the occurrence of much engorgement, a crackling sound is heard, mingling with the vesicular murmur, over the inflamed part; the sound is of the smallest and finest kind of crepitation, similar to that emitted by salt when thrown on hot coals. As the inflammation advances the crepitations become more and more pronounced, until they entirely supersede the vesicular murmur. These crepitations do not remain long; they are superseded either by a return of the vesicular murmur, indicating the resolution of the inflammation by a tubular sound, or an entire absence of sound.—(See Auscultation.)
ETIOLOGY.

The causes of pneumonia are similar to those of bronchitis, laryngitis, &c., namely, exposure to cold and wet, sudden chills, and housing in very cold, draughty stables. Horses kept in ill-ventilated stables are undoubtedly rendered susceptible to many diseases, and to pneumonia amongst the rest, but they will bear impure air even better than cold draughts blowing directly upon them. I have repeatedly observed that the slightest cold contracted by a horse kept in a draughty stable has almost invariably been succeeded by pneumonia, and that if the animal were not removed to a more comfortable situation the disease tended to a fatal termination. It has already been stated that inflammation may succeed the congestive condition induced by severe exertion; it may also be induced by irritating gases; smoke of burning hay and straw; foreign bodies entering the lungs from the bronchi, examples of which are not uncommon in cows, as sequelae to parturient apoplexy, where medicine finds its way into the trachea and bronchial tubes, and in horses choked by irritating and powerful remedies, such as ammonia.

Direct injuries to the lung through wounds in the thoracic walls are not always succeeded by much inflammation, the lungs appearing to have remarkable powers of recovery from direct injury, provided it be not crushed, or that foreign bodies or extravasated blood are not forced into the wound in its tissue.

Pneumonia may also be induced by any material altering the composition of the blood, epizootic influences, purpura, anthrax; accidental products accumulating in the blood; mechanical or solid materials (thrombi) formed elsewhere, and conveyed to the lungs by the blood, as in phlebitis; infecting influences of materials conveyed to the lungs, as in pyaemia or glands. It may be the result of passive congestion arising from disease of the heart or weakness of the circulation, induced by exhausting diseases or old age; or it may be the localization of a specific disease, as in pleuro-pneumonia contagiosa.

SYMPTOMS.

The symptoms of pneumonia, namely, the greatly accelerated respiratory movements, oppressed pulse, and other signs of excitement described by Youatt, Gamgee, and others, are not by
any means diagnostic of pulmonary inflammation. In many cases the breathing in the earlier stages is not difficult, and one is often surprised upon auscultating the chest to find that consolidation has proceeded to a great extent without any very distinct symptoms having been presented.

In the earlier stages, the symptoms are acceleration of the pulse; in very many instances it will average eighty beats per minute; hotness of the mouth, and elevation of the temperature to 103°, 104°, or even 106°; there is a dry, dull cough, coldness of the extremities, and some degree of rigor. In some instances the disease is ushered in by a severe rigor, succeeded by a hot stage; the mucous membranes are red and injected, the conjunctivæ presenting sometimes a rusty yellow tinge; the animal does not lie down, and if loose wanders occasionally about in a dull, depressed manner, now and then eating a mouthful of food. It is stated that the animal stands with its limbs outstretched and head protruded. I have, however, failed to observe this, except in very acute and congestive cases, until the disease has made considerable progress. There is some degree of constipation, but the feces are mixed with flakes of mucus; the bowels are irritable, and do not tolerate purgatives. If complicated with pleurisy, the breathing is more distressing, abdominal, and painful, but in pure pneumonia there is an absence of any very painful symptoms. I have carefully noted the breathing in many cases of pneumonia, and found that the respiratory movements may not be above twenty per minute for several days after attack—a difference so slight from the normal number, that one is apt to overlook it altogether. The observations of Dr. W. Gairdner, that "the dyspnea of pure pneumonia is a mere acceleration of the respiration, without any of the heaving or straining inspiration observed in bronchitis, or in cases when the two diseases are combined," hold good both in horses and cattle; but congestive paroxysms are not at all infrequent during the progress of the malady, during which the breathing is not only greatly accelerated, but also laborious and distressed. As the disease advances, the respiratory movements become somewhat accelerated, until the period of crisis, when usually the breathing becomes much quickened. As a clinical fact, it may be stated that the fever continues for some days—five, eight, or sometimes longer—and that it then gradually subsides, the pul
several beats per minute, the mouth becoming cool, the elevation of the temperature gradually subsiding, the appetite returning; the secretion of urine, which during the febrile period had been scanty, of a high specific gravity, loaded with urea, and deficient in chlorides, is now abundant. Whilst these symptoms of returning health are becoming apparent, it will be found that the respiratory movements are increased in rapidity, and auscultation will reveal the fact that consolidation of the lung increases during the subsidence of the febrile symptoms.

This had led some pathologists to conclude that pneumonia is a specific fever, terminating by an exudation into the lung tissue, in the same manner as varicous fever terminates in an eruption on the skin. I cannot agree with this view, inasmuch as the pneumonia is a concomitant condition from the commencement, and I look upon the exudative process as affording relief to the febrile symptoms, in the same manner as an ordinary swelling gives relief in such diseases as lymphangitis and ordinary inflammation of areolar tissue.

It will be seen that pneumonia is dangerous during two stages: first, during the early fever, which may destroy life by its intensity; and, secondly, during the period of lung hepatization, which may prove fatal by so altering the lung tissue as to produce suffocation.

These, then, are the two periods during which the practitioner has to exercise his skill and care. In some instances death may occur subsequent to the consolidative stage from rapid deliquescence of the inflammatory products, extensive suppuration, or contamination of the blood by degraded exudates absorbed into the circulation.

In human medicine, the absence of the chlorides in the urine during the earlier stages, and their return in increased quantities in the convalescent stage, is looked upon as of great importance. This is a matter which requires further observations in veterinary practice. In some instances, a discharge of a rusty-tinged more or less viscid material from the nose is observed in the horse. This is sometimes streaked with blood; it is not, however, a constant symptom, as in all probability much of what might be expectorated by the human being is swallowed by the lower animals. The character of the discharge is significant; in bronchitis and catarrhal pneumonia it is more or less
purulent, and if excessive, indicates a condition of great
danger. In croupous pneumonia it is amber coloured, viscid,
but not abundant.

It is agreed upon by all observers that a horse will not lie down
during the intensity of any chest disease. This is not a diagnostic
sign of any particular affection of the horse, as it will per-
sistently stand while suffering from many other maladies.

The ox will lie on the sternum during all the stages of pul-
monary diseases.

When the breathing is very rapid, the horse will stand with
the elbows turned outwards, and the toes turned inwards. If
great prostration succeeds, the position of the limbs is altered.
It will then stretch its feet apart; the elbows will be turned
inwards, and it will balance the trunk upon the extremities.

The pulse of pneumonia is very variable; sometimes full, with
a degree of hardness; sometimes full and soft; at other times it
is small, irregular, intermittent, or double—the latter condition
marking a congestive condition of the pulmonary vessels and
right side of the heart and veins, as well as an anemic state
of the arterial system.

In ordinary pneumonia, running its course to a favourable ter-
mination, the period of consolidation, which is indicated by absence
of sound, or a small degree of tubular breathing, is succeeded by
the advent of secondary and larger crepitations, which increase
in number and intensity for two or three days, then, gradually
diminishing, are superseded by the normal respiratory sounds.

To sum up, it may be stated that the diagnostic signs are those
revealed by auscultation and percussion. First of all, small
crepitations, indicating injection of the nutrient arteries and
dryness of the lung tissue; secondly, tubular breathing, or
absence of sound, indicative of engorgement and consolidation,
and thirdly, the reappearance of the crepitations, now of a
larger character, pointing out that the exudate is undergoing
metamorphosis, and becoming absorbed.

The secondary crepitations are sometimes of a bubbling char-
acter, and if associated with sunken eyes, a wrinkled expression,
and feebleness of the pulse, indicate a condition of great gravity,
either of extensive suppuration or of moist gangrene. Both these
conditions may be associated with factor of the breath, the latter
particularly being accompanied by a horrible odour.
INFLAMMATION OF THE LUNGS.

During all the stages of pneumonia, increased dulness is elicited by percussion.

Inflammation of both lungs, or double pneumonia, must be regarded as a source of very serious danger from the great impediment it presents to the breathing, and deaths from it are much more numerous than from the single form. It is, however, very rarely met with.

Pneumonia is sometimes latent, and may remain undiscovered perhaps until after the animal's death. In all cases of ill-defined maladies, it is necessary that the chest be thoroughly examined, when disease of a very grave nature may occasionally be detected, although the animal has never presented any very evident signs of serious lung disease.

During the prevalence of epizootics, pneumonia is apt to assume a marked adynamic or typhoid form, attended with an early breaking down of the pulmonary tissue. This is, however, rare, and the most common form of chest disease met with is a combination of pneumonia with pleurisy, in which the symptoms of both diseases are inseparably blended.

Acute pneumonia, especially if associated with bronchitis, is sometimes complicated with laminitis or inflammation of the feet.—(See Principles and Practice of Veterinary Surgery.)

Acute inflammation may terminate in a chronic form of pneumonia, in which the inflammatory products undergo fibrous or caseous degeneration, keeping up a continued degree of irritation, unfitting the animal for work, and gradually destroying life by inducing anemia, glanders, or hydrothorax. The symptoms of non-contagious pneumonia and pleuro-pneumonia in the ox are much more acute than those of pleuro-pneumonia contagious.

Hemoptysis, or bleeding from the lungs, is not generally associated with pneumonia, but may be witnessed in congestion, accidental rupture of vessels, glanders, purpura, and in a passive form in some epizootic disease or influenza; in which case I have seen the blood of a dark colour, and not frothy as in ordinary hemoptysis.

TREATMENT.

Bleeding.—The abstraction of blood was considered the sheet-anchor in pneumonia. Percivall says—"I will take it for granted
that pneumony, either in its congestive or inflammatory form, has set in; which being the case, it becomes the imperative duty of the practitioner, without any regard whatever as to the state of the pulse or the condition of his patient, to abstract blood the moment he is called in. Generally speaking, a large orifice in the jugular vein is to be preferred to a small one; in cases of imminent danger it is absolutely indispensable. The quantity of blood to be abstracted must be as great as the patient will bear; and our sure guide in this is the effect which the efflux of blood has upon the pulse at the jaw. While the blood is flowing, keep your fingers applied upon the submaxillary artery; so long as you feel that pulsating, so long may the stream of blood be continued; but the instant the vessel collapses under the pressure of the fingers, and pulsation is no more perceptible, let the blood can be removed and the vein pinned up. . . . The quantity of blood we shall be able to draw on the first occasion will vary in different subjects and under modified circumstances; it may amount to a couple of gallons, it may not exceed a couple of quarts. . . . A second blood-letting is often borne better than a first. When the quantity taken in the first instance has has been but small and inadequate, if we will only wait a few hours until reaction appears to have taken place, we shall commonly be able fully to accomplish our object. Six, twelve, or twenty-four hours after the first full blood-letting, guided by the exigencies of the case, principally by the state of the breathing and pulse, it may become necessary to repeat the bleeding, regulating the quantity, as before, by the perception of the pulse at the jaw. I have found it requisite to bleed thrice during the first eighteen hours.”—(Percivall's Hippopathology.) This was the belief and doctrine not only of Percivall, Youatt, and others, but of Professor Dick, who taught and maintained its correctness up to the time of his death. A glance at the pathology of the disease, no less than actual statistics, will enable any unprejudiced observer at once to see the fallacy of the doctrine; and veterinary surgeons, with but few exceptions, have been long convinced that bleeding most materially increases the mortality of the disease. The experience of the medical profession has led them also to arrive at a similar opinion, and Dr. Wilson Fox, in Reynolds' System of Medicine, sums up the conclusions upon this head as follows:—
"(1.) That indiscriminate bleeding immensely increases the mortality of the disease.

"(2.) That it is especially fatal in old people and young children, in patients of exhausted constitutions, and in those suffering from chronic diseases, and particularly in Bright's disease.

"(3.) That it is absolutely unnecessary in the majority of cases of young adults and also young children.

"(4.) That in the vast majority of cases it has no influence whatever either in cutting short the disease, or in lessening its duration or diminishing the pyrexia, but that occasionally these results appear to follow its use when practised early.

"(5.) That in the majority of cases it hinders the critical fall of temperature and delays convalescence.

"(6.) That in the majority of cases, as shown especially by Dr. Bennett's and Dietl's data, recovery is equally, if not more rapid, when it is not practised as when it is resorted to.

"(7.) That in a few cases a moderate venesection may be necessary in the early stages to avert immediate danger of death from asphyxia."

The above conclusions have reference to moderate bleeding only, repeated bleedings being condemned by Dr. Fox as "a system whose impropriety it is scarcely needful to discuss further."

Bleeding, then, can only be safely practised in the very earliest stages of a few exceptional cases, in which symptoms of dyspnoea are very urgent; and even then it must not be pushed so as to debilitate, for more horses die from the prostration of strength at later periods than from the occasional suffocative effects of the earlier and congestive stages.

Bleeding in some cases, no matter when it is practised, seems to afford a relief to the breathing, but this effect is only temporary, and disappears in a very short time, the rapidity of the respiratory movements in pneumonia being dependent on oedema or consolidation, conditions upon which the withdrawal of blood can have but little or no effect.

Convinced of the inutility and danger of venesection, many veterinarians, undoubtedly influenced by the teaching of Dr. Tod, fell into the other extreme, and treated pneumonia by large and repeated doses of stimulants. What possible good effect
this kind of treatment has upon an ordinary case of pneumonia is beyond my comprehension; it can only add to the irritation of the inflamed part, and increase the amount of exudation, if pursued in the earlier stages. I have seen it extensively tried, and must confess the results have been anything but satisfactory. In the later stages, during the deliquescence and absorption of the exudate, if the pulse be small, or in any degree presenting the double or dicrotonous character, when the system is depressed by the obnoxious effects of large quantities of effete materials in the blood, moderate doses of stimulants are both necessary and beneficial. The practitioner should, however, wait until the consolidative stage has to some extent disappeared, and secondary crepitations established. Four or six ounces of whisky or brandy may then be given two or three times a day; not every hour, as recommended by some practitioners. The effect of the first doses must be carefully noted; if they stimulate the appetite, they are to be repeated; but if they cause distress in the breathing, or any signs of exacerbation, they are to be discontinued.

During the pyrexia from seven to ten drops of Fleming's tincture of aconite may be given with advantage. It appears to exercise a beneficial influence, allaying irritation and lowering the temperature both in horses and cattle, and is to be preferred to opium, belladonna, or any other sedative. In the dog, the hydrate of chloral is to be preferred to aconite. The bromide of potassium or ammonium also exercise a calmative effect, and may be given to all animals in suitable but not large doses.

Calomel, opium, digitalis, tartar emetic, seem to have no effect in curtailing the duration of the malady. Opium is only admissible when the pneumonia is associated with pleuritic pain.

Purgatives are inadmissible in the horse on account of the sympathetic and irritable condition of the alimentary mucous membrane.

If constipation be extreme, enemas, or a small dose of oil, are to be preferred to the more active cathartica. Aloes is contra-indicated, and should never be given. In horned cattle a saline cathartic may be given in the early stages, for the purpose of unloading the stomachs and alimentary canal, and thus give greater freedom to the respiratory movements.

Nitrate of potash given dissolved in the animal's drinking
water seems to diminish the amount of exudation, and modify the fibrinous condition of the blood. It has also a cooling or detergent effect upon the system generally, modifying the pyrexia, and, by acting upon the kidneys, assists in the excretion of effete materials from the blood. In some instances, particularly when the kidneys remain torpid, its diuretic effect is increased by a few doses of colchicum. But the administration of the nitre or the colchicum should not be persevered in too long, as they both tend to debilitate, and whenever free diuresis is established, they should be discontinued. In some instances, particularly if the patient be debilitated or out of condition, spirits of nitrous ether may be substituted for the potash salt.

Blisters.—For many years I have held that the application of the so-called counter-irritants, whether they be cantharidine blisters, mustard, turpentine, or any other powerful irritant, is not only useless but dangerous in the earlier stages, and uncalled for when convalescence is progressing favourably.

In the earlier stages, they add to the distress, prevent the freedom of the respiratory movements, and increase both the fever and fibrinous condition of the blood; and large cantharides blisters, the cantharidine of which is absorbed into the blood, induce a condition of blood poisoning characterised by albuminuria and great prostration, and by irritating the urinary passages increase both the distress and the fever. I am glad to find that this conclusion—a conclusion, I may state, which has met with much opposition—is endorsed by physicians. Dr. Wilson Fox says—"Blisters, in the earlier stages of pneumonia, are to be considered as both useless and as greatly increasing the distress of the patient. When resolution is progressing favourably, they also appear to be quite unnecessary. In a few cases when resolution is delayed, or when there is evidence of a small amount of pleuritic effusion, they may, I believe, in adults be occasionally employed with apparent advantage. In children they are almost invariably inapplicable. Warm fomentations or poultices to the sides often give great relief to the pain. I have by no means satisfied myself that any advantage accrues during the acuter stages from any more irritant applications, whether mustard or turpentine, though in cases of threatening collapse, or when dyspnoea is severe, they have occasionally appeared to afford relief."—(See REYNOLDS' System of Medicine, vol. iii., p. 701.)
In the horse the application of either mustard or turpentine causes very great distress, a high state of excitement, an increase of the febrile disturbance, and often tends to hasten a fatal termination. For these reasons the indiscriminate employment of such remedies is highly condemnable. Warm fomentations to the sides, however, afford relief; and they should be persistently employed in all cases marked with rapidity or distressful breathing.

When the extremities remain very cold, the return of warmth and circulation will be much assisted by frictions, or the application of a mild embrocation and bandages; and, to sum up, it may be stated that the successful treatment of pneumonia consists in the following essentials:—1st. Placing the patient in a well-ventilated loose box, where the air is pure, abundant, but not too cold. The necessity of pureness of air will be understood by reference to the observations of Sir Thos. Watson quoted at page 559. If the air be impure, suppuration of the lungs to an extreme extent will be apt to be established, as impure air contains organic germs in great abundance, and these, gaining access to the inflamed part, increase the tendency to the formation of pus. In the winter months, especially if the weather be cold, I have noticed that coldness of the air increases the pulmonary inflammation, and that after a very cold night an animal has been in a state of approaching collapse in the morning. To prevent the occurrence of the mortality from the above cause, veterinary establishments ought to be furnished with loose boxes, where the air can be artificially warmed to a temperature of at least 70° F. 2d. The surface of the body, extremities, and head are to be kept warm by suitable, but not too heavy, clothing; frictions, and the application of non-irritating stimulants to the extremities, being useful in cases where they are deathly cold. 3d. The horse is to be allowed as much cold water as it will drink; but it is not advisable to allow it to drink a large quantity at once. If it be permitted free access to water whenever it pleases, by placing it in its box or stall, it will generally partake of it in sufficient but not over-abundant quantity. 4th. The febrile condition must be treated according to the intensity of the symptoms. If the fever be high, aconite and nitrate of potash are to be administered, but if, on the contrary, the fever be of an adynamic type, carbonate of ammonia
with camphor may be given in the form of a ball, in addition to the potash nitrate. 5th. If the bowels be constipated they are to be carefully regulated by a moderate dose of oil, and by enemas. 6th. During resolution of the inflammation care must be taken that nothing be done to check the action of the excretory organs. Should moderate diarrhoea or increased diuresis come on, they are on no account to be checked, as they are merely critical discharges, whereby the effete materials in the blood are eliminated from the economy. 7th. In the earlier stages the food is to be simple, laxative, cooling, and nutritious. Bran and boiled linseed mashes, a moderate allowance of good hay, roots if in winter, or grass if in summer. During the later stages strong food, as oats, beans, with grass or roots, are to be allowed in moderation; and should the appetite be bad, stomachic stimulants, as spirits of nitrous ether, with gentian or nux vomica, are useful adjuncts; but should the patient refuse to feed, milk and eggs are to be freely supplied. This it will drink if stinted in its water; it should never be forced upon it by horning, nor should gruels, hay tea, large doses of ale, porter, &c., be forced upon it.

I may state, in conclusion, that in all cases where depression and debility are prominent symptoms, with a small, feeble, rapid pulse, stimulants should be cautiously used, and if after a few doses they appear to do no good, they are to be discontinued, and the case left without much meddling or interference; and that bleeding is but rarely called for, and only in cases where the dyspnœa is great, and the danger to life imminent. Even then it is not to be pushed to the extreme recommended by some writers and teachers.
CHAPTER LIIL

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(1.) DISEASES OF THE RESPIRATORY ORGANS—continued.

PLEURISY—PLEURITIS.

Inflammation, partial or general, of the serous membrane that lines the cavity and covers the viscera of the thorax, attended with effusion of serum, exudation of lymph, or, rarely, the formation of pus.

Pleuritis, or a combination of it with pneumonia, is the most common form of chest inflammation met with during the prevalence of the easterly winds of spring and early summer, and has been fully described at page 346.

In the lower animals, exposure to cold is the most common cause of pleurisy. It has followed clipping when an animal has been exposed to cold, and Duvieuxart states that he has seen three hundred cases of pleurisy in a flock of sheep shorn in February, thirty of which died.—(GAIGEE's Domestic Animals.) It will sound strange to veterinary surgeons to be told that cold is now believed to have no effect in causing pleurisy in the human being: such, however, is the belief.

Undoubtedly pleuritis in the horse often partakes of a rheumatic character; the inflammation being induced by the same cause—cold—and assuming a similar metastatic type and character, changing its seat from the pleura, sometimes to the pericardium, endocardium, or to the ligamentous or tendinous structures of the extremities. In more than one instance navicular disease has succeeded an attack of pleurisy, and I have one specimen in my possession showing ossification of the heart,
caries and eburnation of the navicular bone, as results of acute
navicular arthritis succeeding an attack of rheumatic pleurisy.

At the outset the inflammatory phenomena commence in the
subpleural tissue, the blood-vessels of which become congested.
At first the congestion presents an irregularly spotted appear-
ance; the spots, however, multiply rapidly, and the red colour
becomes diffuse by their confluence.

In other instances the pleural surface presents a streaky
appearance, whilst in others the whole of the pleura, pulmonalis
and costalis, presents a bright red congested appearance over its
surface. The secretion of the pleural surfaces is at first sus-
pended, and if the ear be applied to the side of this stage a dry
friction sound will be heard.

The dryness of the membrane is very shortly succeeded by
effusion of serum, and the formation of an exudate which has a
tendency to become organized into a false membrane, causing
the adhesion of the two pleural surfaces.

It is important that the time in which these false membranes
may be formed be clearly ascertained. The experiments of
Andral throw some light upon this subject, which is important
to the veterinarian as a question of jurisprudence.

Andral made experiments upon the pleura of rabbits by
injecting acetic acid into them.

He sometimes found at the end of nineteen hours soft, thin,
false membranes, traversed by numerous anastomosing red lines.

In other rabbits, placed under circumstances which appear to
be exactly similar, no such result had taken place at the end of
a much longer period; and the pleura contained only a serous
or puriform liquid, mixed with unorganized flakes of lymph.

Experiments performed by myself upon healthy subjects
(horses) in 1874 proved that a false membrane, presenting some
degree of organization, may be found in twenty-four hours after
the injection of an irritant into the pleural sac, and that the
puriform appearance mentioned by Andral is an evidence of an
inflammation of longer standing, arising from degeneration of the
inflammatory products.

It may be briefly stated that all cases of pleuritis terminate
not only in the formation of an exudate—which may become
finally organized into a permanent false membrane, or may liquify
by fatty degeneration, and be eventually absorbed—but in the
SPORADIC DISEASES.

Effusion of serum, constituting limited hydrothorax; that extensive hydrothorax, even to invasion of the walls of the thorax, is a natural result of a diffuse and intense inflammation; and that in pleuro-pneumonia contagiosa of the ox there is often oedema of the thoracic walls without actual hydrothorax.

Pleurisy may be either double or single; generally it is single, and confined to the right side.

Pleurisy is sometimes, but very rarely, caused by direct violence to the thoracic walls.

SYMPTOMS.

The disease at the outset is characterised by some degree of rigor, very often a mere chill, manifested by a staring coat, and coldness of the surface of the body. This is, however, succeeded by signs of pain, often mistaken for colic, during which the horse paws, and perhaps lies down and rolls; it eventually becomes stiff and sore, and if suddenly approached or if rapped upon the affected side, will groan. The acts of respiration are performed rapidly and incompletely, the ribs are fixed, the respiration is mostly abdominal, and a hollow line extends along the interior border of the false ribs, from the sternum across the flank to the anterior spine of the ilium. A dry, short, painful cough supervenes; the pulse is hard and quick. If the side be closely examined, the muscles covering the affected part will be noticed to tremble or quiver; this lasts but a short time only, and is succeeded by diminished motion. These signs, as well as the pain upon pressure, indicate that the intercostal muscles participate in the inflammation, and that pleurisy is generally associated with pleurodynia, first described by Haycock.

When the pleurodynia, or inflammation of the muscles, is very intense the animal moves in a very rigid manner, steps slowly and very short; is greatly dejected, the back is arched, the skin exhibits great tenderness when subjected to pressure. I may state that I have seen some cases that were so stiff and sore as to fall when compelled to move.

Hydrothorax.—When an animal dies of pleurisy, especially if it has survived the first stage, a considerable amount of effusion of serum will be found, constituting dropsy of the chest, or hydrothorax. In some instances a large quantity may be found in a day or two, and in some rare cases without any perceptible
disease of the pleura. The symptoms of hydrothorax are short, quick, laboured respiration; the pulse small, quick, soft, often intermitting; auscultation reveals absence of sound in the inferior part of the chest, or a sound resembling that of drops of water falling into a well, as has been already explained. The hydrothorax in the horse generally invades both sides of the cavity of the thorax, for a communication exists owing to the loose diaphanous or web-like structure of the mediastinum, as pointed out by Rigot, De Lafond, and Bouley. This natural communication is in some instances obliterated by exudation of lymph on the mediastinal surface, in which the hydrothorax will be confined to the one side. In other instances the serous effusion, confined in sacs of adventitious products, will be confined to certain circumscribed parts of the chest only. The liquid effused is composed of serum mixed with flakes of lymph, and is generally more or less clear upon the surface, turbid in the lower parts from admixture with particles of exudative materials; it is sometimes, however, tinged with blood. If the clear liquid be placed in a glass and left at rest, it generally separates into clot and serum, proving that it contains the constituents of fibrin, which conglutinate on exposure to the atmosphere.

In forty-three cases observed by M. St. Cyr, the effusion from the first to the seventh day presented a port wine colour in nine cases, a sero-sanguineous appearance in six, muddy or greyish in three. From the eighth to the fifteenth day the port wine colour was observed in two, the sero-sanguineous in three, muddy greyish in four, and limpid in six. From the sixteenth to the thirtieth day the colour was limpid in five cases, and after the thirtieth it was also limpid in three cases. M. St. Cyr draws the conclusion that the liquid begins to clear up towards the end of the second week, and that it is clear after the twenty-fifth or thirtieth day, and that this is the epoch from the acute to the chronic state of pleurisy.

English veterinarians generally maintain that the advent of hydrothorax is manifested by an apparent improvement of the pleuritic symptoms. They state that the pulse falls, the breathing becomes easier, &c. This is so far true, but is not diagnostic, as the abatement of the symptoms indicates the subsidence of the pain and fever, and that the dry condition of the pleura has passed on to that of increased effusion, its natural sequence.
Now, if the effusion continue or remain unabsorbed, or is poured out in greater quantities than can be taken up by absorption, it naturally follows that the condition of hydrothorax will be the result; if, on the contrary, the effusion be moderate in quantity, or if absorbed, it as naturally follows that the improvement of the symptoms is but the forerunner of convalescence.

In addition to increasing difficulty of breathing, a difficulty sometimes so great as to call into operation the action of muscles other than those of respiration, extending even to the caudal ones, causing an upward and downward motion of the tail similar to that of a pump handle, the other characteristic signs are dropical swellings, commencing generally at the sternum, extending along the floor of the abdomen, and finally invading the areolar tissue of the extremities; flapping of the nostrils, protrusion of the head, and increased roundness or bulging of the ribs, and the hair of the mane and tail is easily pulled out. In some instances of hydrothorax the legs remain unnaturally fine, even to the fatal termination.

It may be mentioned that the appetite is capricious, and that the symptoms generally are subject to variations—the diagnostic ones being those detected by percussion and auscultation.

TREATMENT.

The treatment of pleurisy in its acute stage differs but little from that of pneumonia, unless, indeed, the pleuritic pain be acute, then opium is essentially necessary. In the very earliest stage of the inflammation, when the pain is usually most acute, a dose of tincture of opium, in combination with a pint of linseed oil, has usually a very decided anodyne effect, particularly if its soothing effect be assisted by warm fomentations to the affected side. The opium may be repeated if the pain continues; usually, however, the acute pain subsides in a few hours; and, provided the pulse remain hard, aconite may take the place of the opium. If the pulse be soft and showing little irritation, but little treatment, beyond warm fomentations to the sides, clothing the animal warmly, allowing it to drink freely of cold water, in which an ounce of potash nitrate is daily dissolved, and supplying it with nutritious, easily digestible food, is necessary. The fomentations to the sides are
PLEURISY.

not, however, to be neglected, so long as the breathing remains at all laborious; experience having taught me that they not only soothe the irritation and pain, but that they most materially promote convalescence, and diminish the tendency to hydrothorax and death.

Bleeding, although often indicated by the hardness of the pulse, seldom does any good; it certainly has no effect on the duration of the disease, even in cases where its primary effects have seemed to afford relief to the pain and respiratory embarrassment; and in the majority of instances where it has been indiscriminately performed, it has delayed the convalescence, increased the tendency to hydrothorax, and increased the rate of mortality.

**Blisters.**—Of the application of the so-called counter-irritants, I can only repeat what I have taught, that with rare exceptions they are injurious. Veterinarians, however, generally maintain otherwise; and in support of their arguments appeal to the practice of physicians, who, with rare exceptions, until lately practised this method of treatment. Within the last few years opinion has greatly changed; and in the latest book on medicine, namely, "Reynolds," Dr. Austin, article Pleurisy, page 942, vol. iii., says—"The treatment by so-called 'counter-irritation,' as pursued by many physicians, is no less repugnant to me than is that by mercury or bleeding. Let me make two admissions:—In the first place, the mere application of a mild mustard plaster, or, still better, of a hot poultice or epithem, undoubtedly may give some ease, perhaps even arrest incipient inflammation; and the use of 'small flying' blisters, in the limited attacks of pleurisy, which are so common in phthisis, undoubtedly appears to give relief in many cases. But the use of large blisters, especially if kept open, appears to me both useless and often prejudicial." I need not here repeat what must be already self-evident, that blisters, especially those extensive ones ordinarily applied, only increase the pain, the embarrassment of breathing, the general febrile condition, and the tendency to excessive effusion and exudation. There are instances, however, in which the application of a moderate mustard liniment proves beneficial; these are the cases in which the disease makes but little progress towards recovery, in which the symptoms remain without much alteration for better or worse for some days. This con-
dition is characterised by languor, prostration of strength, a pulse standing about eighty, with scanty secretion of high-coloured urine, a continued elevation of the bodily temperature, capriciousness of the appetite, and a respiratory embarrassment.

From the tenth to the fourteenth day after attack, the above symptoms being present, the application of the mustard liniment, and succeeding warm fomentations to the sides, promotes the absorption of exuded materials, stimulates the system generally, and increases the excretion of effete materials from the economy, evidenced by diuresis, improvement of pulse and respiratory movement, and a rapidity of convalescence, which otherwise could not have been established. In thus applying the cutaneous stimulants care must be taken that their effects do not exceed that of stimulation or gentle irritation; if the application be sufficiently strong to induce soreness of the sides, it is calculated to do harm, not only by increasing the pain, but also by exaggerating the adynamic or typhoid condition. In no instance where resolution is progressing satisfactorily should this treatment be applied.

The colchicum, as recommended for pneumonia, may advantageously be administered in combination with iodide of potassium, or the vegetable or mineral tonics, as the case may be, when absorption and excretion of the inflammatory products are not progressing satisfactorily. When debility and anaemia are associated symptoms, I have found the salts of iron, more especially the tincture of the terchloride, to have a marked effect in promoting the absorption of the inflammatory products, fluid and solid. I have a far higher opinion of the effects of iron salts than of iodine or iodide of potassium. The practitioner is, however, at liberty to combine the iodine with the iron.

*Paracentesis Thoracis.*—In all cases where effusion is excessive, no time should be lost in giving relief to the symptoms of distress by the operation of tapping. I do not mean to advocate early tapping in cases of effusion, being strongly of opinion that absorption of the fluid is calculated to save more lives than its evacuation; but when danger to life is imminent from its excessive quantity, the operation should never be delayed until prostration and debility are associated with the dyspnœa. The most successful method of performing paracentesis thoracis is by
PLEURISY.

means of an instrument, consisting of a trocar and cannula, guarded by a tap, by which a small quantity of the fluid is withdrawn, the exact nature of which can be identified. If fluid be present it can be withdrawn, an elastic pipe being attached to the tap, and the serum allowed to flow into water. Should the fluid be purulent or too thick to flow through the cannula, a suction syringe is to be applied, the force of which is to be sufficiently strong to cause its evacuation.

Dr. Bowditch’s rules for performing this operation are as follows:—“Find the inferior limit of the sound lung behind, and tap two inches higher than this on the pleuritic side, at a point in a line let fall perpendicularly from the angle of the scapula. Push in the intercostal space here with the point of the finger, and plunge the trocar quickly in at the depressed part; be sure to puncture rapidly, and to a sufficient depth, as you may be balked by the loose membranes occluding the cannula.

“It will sometimes happen that with the greatest care and trouble we are unable to get a flow of fluid at the part where we first puncture; it is then our duty to try elsewhere, for our failing may be owing to unusual thickness of the false membranes in the lowest inch or two of the pleural cavity. We thereupon repeat the puncture a little higher up, and further towards the axillary line, and here we perhaps find fluid; at any rate no harm has been done by the two punctures.

“The circumstances under which paracentesis ought to be performed for pleurisy are the following:—

“1st. In all cases of pleurisy, at whatever date, where the fluid is so copious as to fill one pleura, and begins to compress the lung of the other side; for in all such cases there is the possibility of sudden and fatal orthopnea.

“2d. In all cases of double pleurisy, when the total fluid may be said to occupy a space equal to half the united dimensions of the two pleural cavities.

“3d. In all cases where, the effusion being large, there have been one or more fits of orthopnea.

“4th. In all cases where the contained fluid can be suspected to be pus, an exploratory puncture must be made; if purulent, the fluid must be let out.

“5th. In all cases where a pleuritic effusion occupying as much as half of one pleural cavity has existed so long as one month, and shows no sign of progressive absorption.”
In our patients the puncture can be made in the fifth or sixth intercostal space, and as near to the anterior margin of the rib as possible. It is usual to divide the skin with the lancet, and to stretch it before introducing the trocar, so that, when the fluid is withdrawn, the external wound is not directly opposed to that in the tissues. By this method admission of air into the cavity of the thorax is prevented.

Physicians are agreed that it is not necessary to extract the whole of the fluid, and that the removal of just so much as may be necessary to relieve substantially the mechanical distress will, in most cases, give the necessary spur to the natural process of absorption, by means of which the rest of the fluid will be taken up. Should the cannula become blocked up by fibrinous coagula, and the escape of the fluid thus prevented, a whalebone probe must be introduced.

After being tapped all animals are to be supplied with nutritious food—milk, eggs, &c.—if they do not feed, and supported with stimulants and tonics; care being taken at all times that the various excretory organs be kept performing their functions.
CHAPTER LIV.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(K.) DISEASES OF THE HEART AND ITS MEMBRANES.

Heart Diseases, although rare in the lower animals compared with their frequency in man, and much more difficult of diagnosis, are neither infrequent nor unimportant.

For the convenience of description they may be arranged under two heads, namely—1st. Diseases of the heart and valves; 2d. Diseases of the cardiac membranes.

1st. Diseases of the heart are divided into functional and organic.

(a.) Functional derangement of the heart, characterised by palpitations, irregularity, or intermittence of the pulse, may arise from debility, indigestion, blood poisoning, as in purpura, haem-albuminuria, epizootic catarhal fever, &c.

Mr. Gangee states that palpitation due to derangement of the stomach—dyspeptic palpitation—is, as far as he is aware, unknown in the lower animals. I have repeatedly seen this form both in the horse and dog, disappearing when the indigestion was overcome, and reappearing with another attack of indigestion. Palpitation also arises from nervousness. For example, if a nervous animal be approached rapidly and roughly, the beatings of the heart are often distinctly heard; and if the pulse be felt, it may be irregular and intermitting. If one were immediately to form a diagnosis that these results were due to heart disease, a few minutes' further observation would point out the error.

Palpitations and irregularities are symptomatic of other disorders, when they occur occasionally only, and when other signs
of heart disease are absent; if persistent, they indicate, separately or conjointly, some organic lesion of the heart or its membranes. Repeated examinations of the patients are necessary before forming a conclusion.

(b) Organic Diseases.—Carditis, or inflammation of the substance of the heart, is always circumscribed; a general or diffused inflammation, which would be immediately fatal in consequence of destruction of function, is fortunately never witnessed. Partial or circumscribed carditis, unless it be due to injuries, and associated with exocardial effusion and exudation, presents no symptoms during life, and is only discoverable post mortem by the presence of a small abscess or circumscribed deposits of lymph; but although the cardiac walls are not subject to inflammation, they undergo various alterations inimical to the well-being of the animal, and may be described as follows.

1. Hypertrophy.—This may be of three kinds:—

(1.) Simple hypertrophy, where the walls are merely thickened without alteration of the cavity.

(2.) Eccentric hypertrophy, where the walls are thickened and the cavities enlarged.

(3.) Concentric hypertrophy, where the walls are thickened and the cavities diminished.

These conditions are manifested by a more or less persistent palpitation or increased cardiac force, the cardiac sounds being often heard upon both sides of the chest. They are due to some obstruction to the circulation consequent upon chronic pulmonary disease, constriction of some of the large vessels, and are best combated by a moderate diet, freedom from excitement, and, if depending upon broken wind or any impediment to the pulmonary circulation, by small doses of arsenic.

The most common organic change which occurs in the hearts of horses and dogs is that due to atrophy and fatty degeneration. This change is generally met with in aged subjects, and in those which have been pampered and irregularly exercised. It is also a result of pericarditis, and as a sequel to epizootic diseases in which the pericardium has been involved. It is also induced by blood affections, as purpura, azoturia, and scarlatina.

During life the progress of atrophy and degeneration is manifested by a more or less slowly increasing debility of the circulation, exemplified by diminished cardiac impulse, irregu-
larity of the pulse, and a tendency to oedema of the extremities, with inability on the part of the animal to perform ordinary labour.

I have repeatedly watched the progress of this disease, and have found that when the animal is near death there has been capriciousness of the appetite, extreme muscular debility, a peculiar rusty-red appearance of the visible mucous membranes, and a want of correspondence between the pulse and the contraction of the heart. The cardiac sounds have been often loud, amounting to palpitation, but the impulse has been feeble, and the pulse weak and irregular, arising from the fact that the feeble cardiac impulse is not transmitted.

In hypertrophy of the heart, more particularly that of the left ventricle, when the walls are increased in thickness, and the cardiac contractions proportionately strong, the blood is propelled into the arteries with increased force, and the pulse is strong and hard, so long as the circulation is unimpeded by aortic obstruction; but when the heart is atrophied, or its walls attenuated, and its cavities enlarged, the pulse will be of the opposite character—soft, weak, and irregular. If the hypertrophied heart's action be intermittent, the strong pulse will be intermittent also; but in atrophy the pulse will be intermittent and irregular, even providing that the beatings of the heart be regular in their succession.

The post mortem examinations reveal the heart apparently enlarged, but the enlargement is due to dilatation of its cavities and attenuation of its walls. The muscular structure of the whole organ presents a pale or fawn-coloured appearance, is soft to the touch; and when examined microscopically, the most noticeable change is the absence of the transverse striae of the muscular fibres, with here and there true fatty degeneration. In the dog, atrophy of the muscular fibres is generally due to fatty infiltration, which, pressing upon the muscular fibres, cause their removal by absorption. But in the horse the organic change takes place in the sarcous elements themselves, by which they first lose their truly muscular characteristics and their power of contractility, and finally become converted into a fatty material.

I cannot recommend any treatment calculated to arrest the progress of this change in the horse, but would suggest that the chlorate of potash (which has the power of arresting some
degenerations) might be administered. For the dog, mild purgatives, regular exercise, and food containing but little fat, constitute the best treatment, for, as already pointed out, the atrophy is simple, depending upon the pressure of the fatty infiltration.

PERICARDITIS.

Inflammation of the pericardium is often associated with epizootic diseases. In the ox it frequently arises traumatically. When not arising from injury, its causes are similar to those of pulmonary diseases and rheumatism, with which it is often associated. There are but few instances of epizootic pleuro-pneumonia in the horse but are complicated with inflammation of the pericardium; indeed, during some seasons, epizootic diseases partake of the rheumatic type, and involve not only the pleura, pericardium, and endocardium, but also the fibrous structures of other parts of the body.

Symptoms.—In addition to general signs of fever, which is often of a severe type, there is a peculiar irritability and hardness of the pulse, indicative of irritability of the heart; the pulse is short, angry beat, and the heart's action is often irregular; sometimes bounding and violent, at other times feeble and fluttering. There is coldness of the extremities, and acceleration of the respiratory movements.

Leblanc, who is followed by Percivall, Gamgee, and others, says that a marked contrast between the violent heart-beats and smallness of the pulse are characteristic signs of endocarditis, and that they are very important in distinguishing endocarditis from pericarditis. I cannot confirm this conclusion, having repeatedly witnessed these symptoms in pericarditis unassociated with disease of the endocardium. Generally, however, both membranes are implicated in the inflammation, and it is a most difficult matter, in the lower animals at least, to distinguish between the two affections.

Associated with this inflammation, spasms or cramps of the superficial muscles are often witnessed. Most frequently the cramps are confined to the muscles of the pectoral region and neck; but occasionally those of the posterior extremities are also more or less violently affected. The physical sign of pericarditis is a to-and-fro friction sound, resembling a rasping murmur.
synchronous with the cardiac movements. This sign is subject to variety in tone and degree, depending upon the nature and extent of the exudation or effusion. If much fluid be present, the sound becomes lost, being replaced by a dull, churning noise; as the effusion diminishes by absorption, the to-and-fro friction sound returns, unless, indeed, the pericardium has become generally adherent to the heart’s surface. If this sound be associated with a deep-seated blowing or bellows murmur, which sometimes begins to be distinguished when the other ceases, or, in the words of Watson, appears to supervene upon it or to take its place, the combination of sounds indicates an affection of both the external and internal membranes—pericarditis and endocarditis. Dr. Stokes says, “that in respect of morbid anatomy, cases of pericarditis may be arranged into three classes. In the first class are to be placed those in which there is a slight though general effusion of coagulable lymph. In the second, those in which there is superadded the secretion of serum in abundance, causing distension of the pericardial sac. In the third class are to be placed those cases in which signs of muscular excitement, if not of myocarditis, are added to the preceding conditions.

“As the disease advances from the first to the last of these forms, there is progressive increase in the violence of the inflammation, denoted in the second form by the occurrence of excessive serous effusion, and in the last by the altered and impaired condition of the heart itself. Death tends to occur by syncope, induced by paralysis of the left ventricle. The muscular substance of the heart is paralyzed, being of a dirty brown or yellow colour, flabby, and easily torn—a condition which speedily leads to passive dilatation of the heart, general cachexia, and dropsy.”

Post mortem examinations, as conducted in the dissecting rooms, go to prove that pericarditis, as evidenced by alterations of structure, is not such a common form of disease as endocarditis. In the human being it is stated that about thirty-three per cent. of cases examined post mortem, varying from the ages of eighteen to thirty-nine, and about seventy-one per cent. from ages between forty-eight and eighty, show white spots in the heart. These white spots are supposed by some pathologists to be due to previous pericarditis, and by others to attrition from rubbing
of the part against the pericardium applied to the sternum, induced by dilatation of the heart or impeded action of the lungs. These white spots are seldom met with in the pericardium of the horse, whilst they are not uncommon on the endocardial surface.

Traumatic Pericarditis.—In ruminants, particularly cattle, foreign bodies often find their way into the pericardium, wounding both it and the heart. Whilst the carditis so induced is circumscribed, and merely surrounds the point of puncture, the pericardial inflammation and exudation involve the whole surfaces of the membrane.

Cattle are exceedingly fond of chewing and swallowing all sorts of substances; for example, nothing seems to give greater pleasure to a cow than to have an old boot or other piece of leather in its mouth, and this it will chew at with evident gratification. An old brush is also a dainty morsel, and I have seen as a consequence of this that the pericardium has been pierced by the brush nail. Many kinds of sharp-pointed materials have been found in the pericardium of cows. I have seen hair-pins, horse-nails, needles. Mr. Gamgee, in his Domestic Animals, has tabulated the observations of many observers, and amongst the foreign bodies found causing pericarditis he mentions—"A knitting needle, a nail, a piece of iron wire two inches, a plank nail, a hair-pin transfixed the heart, pericardium, and reticulum; a table-knife 7½ inches long, passing from the reticulum to the left ventricle; a ramrod 14 inches long, &c. &c."

Some writers suppose that needles frequently pass from the cesophagus to the heart. Such an occurrence is quite possible, but my own experience and that of other veterinarians in this country points to the conclusion that the foreign body finds its way to the heart from the second stomach—the reticulum—first of all piercing the walls of that viscus and diaphragm, and being gradually drawn by the suction action of the heart into the pericardial sac, generally wounding some portion—commonly the apex of the heart itself. Under "Diseases of the Digestive Organs," the frequency of the presence of foreign bodies in the reticulum, and the harm which they sometimes occasion, will be described. At present I need only state that in cases where a foreign body has been found inducing pericarditis, its
course from the second stomach through the diaphragm and mediastinum into the pericardium can be demonstrated post mortem by the presence of a canal or opening, surrounded by walls of lymph, extending from the stomach to the heart; the foreign body itself lying in the canal, generally more or less eroded or worm-eaten by the action of the juices by which it is surrounded.

Sometimes, however, the foreign body, particularly if a substance, such as a needle, which soon rusts, is worn down to a mere fragment, or in some instances has entirely disappeared by chemical decomposition. In other instances it has been found in the cavities of the heart itself. A most remarkable case of this kind is described by Mr. Gamgee. This case happened in the practice of M. Camoin, occurring in a cow eight years old, which presented signs of heart disease. The post mortem revealed the following lesions:—

The reticulum and omasum contained about two and a half pounds of clotted blood. No lesion was found in any of the abdominal viscera, except the reticulum, in the curvature of which was a round yellowish patch, with an oblong orifice towards its centre of one-fifth of an inch in its longest diameter; this orifice was closed by a clot of blood. The yellow patch seemed to be from a softening and thickening of the mucous membrane, and around it the reticulum was adherent to the diaphragm. The opening was continuous, with a flexuous canal capable of admitting a large-sized goose-quill penetrating the diaphragm, pleura, and wall of the left auricle. The pericardium contained three ounces of a reddish serum; the heart was enlarged and more rounded than natural, of a deep reddish colour, and its coronary vessels engorged with blood; the left cavities were filled with blood; the auriculo-ventricular opening more than normally open; and below this orifice was a little particle of wood, arranged transversely, and supported by its extremities on the tendinous cords of the mitral valve, which it pulled down so as almost to close the aorta. This piece of wood, which was a little over an inch long, and as thick as a writing quill, was no other than a pomegranate prickle, which the creature had picked up in its food. The internal aspect of the left auricle and ventricle was of a deep red colour, intermixed with black patches, which penetrated for some distance into the muscular tissue. Three chordae tendinese
were torn, the aorta empty, the right side of the heart had its endocardium of a reddish hue, but with no other discoloration. The pulmonary artery was nearly half filled with very black blood, and the lungs were congested. The whole venous system was engorged with black blood. This case, which is reported much more fully by Gamgee, died on the twelfth day after illness was first observed; and is a rare instance, fully accounted for by the lesions found post mortem, of death succeeding in so short a time.

Traumatic pericarditis is generally manifested very insidiously, diagnostic symptoms being often absent for long periods after the foreign body has been swallowed, no symptoms being present, so long as it remains in the digestive cavity, nor during its course to the heart, until it materially interferes with the functions of that organ. I have repeatedly observed instances where cows have presented no other sign of disease than an occasional attack of flatulence or indigestion, and have been sleek and well-doing, until the act of parturition, when they have rapidly succumbed, and the post mortem has revealed the pericardium immensely thickened, adherent at its surfaces, and the exudate in a condition of organisation, sometimes of a consistence resembling cartilage; the adhesions between the reticulum, diaphragm, and mediastinum and the walls of the canal being so organised as to leave no doubt of the lengthened period since the injury had been inflicted; the act of parturition, more especially the contractions of the abdominal muscles, having evidently altered the position of the hitherto quiescent foreign body, and thus excited a fresh attack of inflammation. More commonly, however, the symptoms of the lesion have become gradually diagnostic; at first symptomatic of indigestion, with capriciousness of the appetite, flatulence, and eructation of gases, and gradual emaciation. After a while, the pulse becomes exceedingly small; the jugular veins are distended; there is also a well-marked jugular thrill or pulse, extending even as high as the bifurcation of those veins, associated sometimes with palpitation of the heart. To these succeed edema of the inter-maxillary areolar tissue, gradually extending down the neck to the dew-lap; in some instances clonic spasms of the superficial, particularly the cervical muscles. Continental writers state that the diagnostic symptoms of traumatic from simple pericarditis
are a loud gurgling cardiac sound and eructation of gases. The gurgling sound is supposed to arise from the greater consistency of the pericardial effusion, and its admixture with various gases. The eructations are supposed to arise from the communication between the pericardium and stomach, allowing the gas formed in the former to pass into the latter, and thence into the mouth. If these latter symptoms were constant, their importance and value would be beyond doubt. I have, however, seen cases in which neither eructations, gurglings, nor splashing were detectable, and in 1857 I reported two cases in the *Veterinarian*, in which absence of all cardiac sounds was mentioned, this absence of sound being ascribed by me at the time to the thickness and plasticity of the exudate rendering all sounds inaudible.

In some instances there is a painful cough and disturbance of the respiratory movements; in other cases cough is absent, and the respiratory movements unaffected, or even slower than natural. The *post mortem* examination tends to prove that the pericardial exudations are of varying ages, and that the animal has suffered from repeated attacks of pericarditis. This conclusion is arrived at by the fact that two or three, or even four layers of exudation, more or less separable one from the other, are found; the older exudate presenting the appearance of a cornaceous change, being in consistence similar to cartilage, and not easily cut with a knife; then another layer of exudation of apparently more recent origin; then another layer or two of more recent origin still. In some instances the pericardial surfaces are intimately adherent one to another; in others they are here and there connected loosely by bands of lymph, separated from each other by a turbid fluid, whilst in others the exudate is prevented from becoming adherent by the interposition of fluid. It is, however, more or less vascular, and gradually assumes the appearance of a villous membrane.

It is obvious that no treatment can be suggested for this form of pericarditis, and it is advisable to make the best of the animal before emaciation renders it worthless. For the prevention of this fatal occurrence, attendants on cattle should be enjoined to see that the food be free from any of the above-named foreign bodies. When cattle are attended by females the danger is greater from the pins, &c. worn in the dress becoming mixed with the food.
The treatment of idiopathic pericarditis must be directed to allay pain and undue irritability. For this end aconite is recommended; if pain be great, repeated doses of opium are to be administered; the bowels are to be kept regular by moderate doses of oil, and the absorption of the effusion promoted by diuretics. It was supposed at one time that calomel had the power of causing the removal of the exudate, and it was consequently largely employed; but its administration is now generally condemned, and Sir Thomas Watson confesses, in the following remarkable words, that the hope which he once cherished that the inflammation could be controlled by the constitutional influence of mercury has faded away. He says—"Pericarditis has been known, not seldom, to spring up while the patient was already under mercurial salivation. I am obliged therefore to recant the advice which I was formerly in the habit of giving in respect of mercury as a remedy for acute pericardial inflammation." If debility be present, the weakened heart must be supported and invigorated by moderate doses of stimulants in combination with opium. Bleeding, except to relieve urgent symptoms in the earlier stages of the disease, had better be withheld, as there is a strong tendency to an early diminution of the cardiac energy. Blisters are not called for in the earlier stages of the disease, but their application may, in some rare instances, be necessary to promote the absorption of the effusion. Tonics, more especially the salts of iron, prove useful in promoting the absorption of the effused fluids, and are to be given alternately or in combination with diuretics or the iodide of potassium. In the rheumatic form colchicum is indicated. Digitalis, so highly recommended by some authors, appears to me to act injuriously; it destroys the appetite, is uncertain in its action on the heart, and, if persevered in, its toxic, cumulative effects are apt to cause serious derangement.

To sum up, it may be stated that warm fomentations to the side, warm clothing, bandages to the legs, with careful administration of remedies calculated to relieve such urgent symptoms as may arise during the progress of the disease, and allowing the animal a plentiful but not over-abundant supply of easily digestible nutritious food, are the general principles of safe treatment. If there be danger of death from hydropericardii manifested by orthopnoea, obstruction to the venous
circulation, and a serious interference with the heart's action, paracentesis is to be performed; a small trocar being used, which is to be introduced carefully at the side of the sternum, between the cartilages of the fifth and sixth ribs.

**Endocarditis.**

As a sequel to articular rheumatism, endocarditis is a more frequent form of disease than the last described one. It is an inflammation of the membrane lining the cavities of the heart, and presents symptoms similar to those of pericarditis; the difference being that in its purity the blowing sound—the "bellows murmur" already referred to—takes the place of the to-and-fro friction sound. The marked venous pulse, and the want of correspondence between the pulse and the cardiac impulse, laid down as diagnostic of this disease by Leblanc and Gamgee, are seen in other cardiac affections, and are of no diagnostic value. I am, however, of opinion that the clonic spasms of the superficial muscles, already mentioned, along with hurried breathing and a tendency to syncope, if the head be suddenly elevated, or the animal in any way disturbed, are more marked in this than in any other cardiac affection. It is very true that in cardiac degeneration there is a tendency to syncope from debility of the circulation. This condition, however, differs from acute endocarditis by the absence of febrile disturbance. Endocarditis is much more fatal than any other acute cardiac affection, for the reasons that it is often associated with a mal-condition of the blood; that it leads to valvular alterations, and to a deposition of fibrinous coagula on the valves, which destroy life by interfering with the circulation of the blood, or, carried away by the blood to other parts of the body, by obliterating the capillaries of other organs, leading to softening, abscesses, or sudden death, or undergoing degradation by poisoning the circulatory fluid.

*Morbid Anatomy.*—The first effect of inflammation of endocardium is seen in the form of red spots, streaks, and patches. The redness is always most intense in the neighbourhood of the valves, which in some instances lose their integrity, and become ruptured or detached from their tendinous cords. Supervening upon this, lymph is exuded both into the substance of the
membrane and upon its free surface. That upon the free surface is often washed away by the current, but, generally speaking, it is found between the folds and upon the free surfaces, constituting warty excrescences upon the valves.

In a specimen now before me, obtained from a cow which had three months prior to death suffered from rheumatic arthritis, there are no less than five-and-twenty of these excrescences, more or less organised, attached to the surfaces of the tricuspid valve. They vary in size from a pin head up to a large nut; some of them being in the auricle and some in the ventricle, attached not only to the valves but to the chordae tendineae, carnae columnae, and musculi pectinati, whilst the spaces between the tendinous cords are filled with coagulated blood. In the left side of the heart there are also traces of deposition within the mitral valve, having the shape of irregular white spots. It will be thus seen that there is not only a deposition upon the free surfaces, but also an exudation in the membrane itself. In some instances the valves become ulcerated, and even the cardiac walls perforated, establishing a communication between the two cavities.

The growths of endocarditis differ from those clots or coagula which form during or after the agony of death, and they must not be confounded with the corpora auranthii, which are generally more or less enlarged in aged subjects. The coagula, which form during or after death, are not adherent to the parietes, are soft and easily removed.

In the treatment of endocarditis particular care must be taken to pursue no treatment calculated to lower the heart's action, as debility of the circulation greatly favours the tendency to coagulation of the blood in the heart, and the consequent formation of these coagula. For the same reason, remedies which have the power of modifying the coagulation of the blood, such as the nitrate of potash, or, when debility is present, the bicarbonate of ammonia, are to be prescribed; and for the reason that inflammations, artificial and natural, increase the fibrinous condition of the blood and its tendency to coagulation, blisters, setons, and all other remedies which constitute the so-called counter-irritant treatment, are to be avoided. The treatment recommended for pericarditis is applicable for endocarditis, with this exception, that those sedatives which diminish the cardiac energy are to be
carefully and cautiously administered. They are certainly useful, more particularlyaconite, in relieving disquietude and irritability; but they should be given in small doses only, and for the reason above stated, that all remedies calculated to lower the action of the heart promote the tendency to fibrinous coagulation.

The results of endocarditis are various diseases or alterations in the form and structure of the valves, leading to ulceration, perforation, pulmonary apoplexy, and ultimately to the death of the animal.

DISEASES OF THE VALVES.

For various reasons, such as the distance of the heart from the thick and muscular thoracic walls, valvular diseases are exceedingly difficult of diagnosis. They are generally due to a change of structure, caused by endocarditis, mechanical rupture, or morbid growths. The result is imperfect valvular action, indicated by difficulty of breathing when the animal is subjected to exercise, the venous or jugular pulse, the so-called vertigo or megrims, sometimes a tendency to oedema of the limbs, and modifications of the cardiac sounds. These modifications are as follows:—A bellows murmur with the first sound indicates mitral disease or insufficiency; a bellows murmur with the second sound indicates aortic insufficiency.¹ Beyond this my experience does not enable me to describe more definitely any train of symptoms which are of diagnostic value. Indeed, I have repeatedly found the cardiac sounds modified, a distinct venous pulse, and irregularity of the heart’s action in various conditions unassociated with valvular diseases. For example, the jugular pulse, which would lead one to conclude that the regurgitations were due to tricuspid incompetency, is generally present in various alterations of the cardiac walls, and in pericarditis, whether it results idiosyncratically or traumatically. Practically it may be stated that an animal suffering chronically from the above symptoms is only fit for the slowest kind of work.

Various kinds of new formations—tumours, parasitic growths—are sometimes found in the heart. These are very fully

¹ Mr. Robinson, Sen., Greenock, relates a case in which there was a loud booming murmur in the direction of the great arteries, along with a strong pulsation of the posterior aorta, femorals, &c., which could both be seen and felt. The post-mortem revealed rupture of the aortic semilunar valve.
described by Gangee in his *Domestic Animals*, to which the reader is referred.

**ANGINA PECTORIS.**

The condition termed angina pectoris, or breast-pang, a disease characterised by agonizing pain and distress in the human being, undescribed, so far as I am aware, in the lower animals, is a form of disease which I believe sometimes affects the horse. This disease, in man, is defined as a pain or spasm referable to the lower part of the sternum, extending to the left scapula and root of the neck, and manifesting itself in paroxysms of great severity. I feel confident that in one horse I have seen this condition in a well-defined form. The subject in question was an aged cart-horse brought for my examination in the year 1873. For twelve months previous the horse had done but little work, owing to the fact that when he was excited by work or exercise he manifested the most exquisite agony in the near (left) fore limb, the muscles of which, more particularly the pectorals and those of the neck, became violently convulsed, the limb itself being alternately rigidly fixed by muscular contraction and powerlessly paralyzed, so that the animal was quite unable to use it, and if forced to move be painfully dragged the limb, or sometimes fell to the ground. Whilst at rest the paroxysms seldom occurred, but I noticed that there was a continual spasmodic twitching of the above-mentioned muscles, as well as a dread on the part of the animal when suddenly approached. On examining the heart and circulation there was a distinct jugular pulse, great irregularity of the heart's action, a loud cooing or blowing sound and strong impulse, indicative of hypertrophy, and such a want of correspondence between the cardiac energy and feeble pulse as to lead me to the conclusion that the horse was suffering from valvular incompetency or impediment, to overcome which hypertrophy of the cardiac walls had become established.

Angina pectoris is supposed by physicians to be due to dilatation of the cardiac cavities, degeneration of the walls, some condition of the aortic valves which permits the regurgitation of blood into the heart, or some sudden impediment to the coronary circulation. The condition of the horse in question pointed to the conclusion that the cause was due to aortic impediment. Unfortunately I lost sight of the animal, and I am unable to
DISEASES OF THE HEART AND ITS MEMBRANES.

confirm this view by any post mortem examination. The latest theories upon the cause of this painful malady are as follows:—

(1.) Neuralgic affection, commencing for the most part in pneumogastric nerve, and spreading in different directions.

(2.) That it is due to such an acceleration of the movements of the blood, by exercise or otherwise, that it arrives at the heart faster than it can be transmitted onwards, and accumulates in its cavities so as painfully to distend them.

(3.) Ossification of the coronary arteries, which, by failing to supply sufficient blood to the cardiac walls, so impairs their strength that the heart is incapable of contracting upon the increased quantity of blood within its cavities, brought about by exertion or excitement.

CYANOSIS.

The blue disease described by some veterinary authors, and depending upon non-closure of the foramen ovale, is a condition which is only met with, and that very rarely, in very young animals. It is due to admixture of the venous with the arterial blood in the left cavities of the heart, owing to the foramen of communication existing in foetal life remaining pervious after birth. It is manifested by blueness of the visible mucous membranes, difficulty in breathing, and coldness of the surface. Animals so affected live but a short time after birth.

ECTOPIA CORDIS.

Misplacement of the Heart.—The most common form of cardiac misplacement is that in which the heart is situated outside the chest. I have a specimen in my possession in which both ventricles and auricles are outside the chest, and in which the heart communicates with the interior of the body through a large foramen in the sternum.

Note.—A very useful Lecture on the Diagnosis of Disease of the Heart, by George W. Balfour, M.D., F.R.C.P.E., is published by Macleod and Stewart. My knowledge of heart disease in the lower animals does not, however, enable me to take advantage of the delicate signs and tests therein described.
CHAPTER LV.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(L.) AFFECTIONS OF THE DIAPHRAGM.

SPASM OF THE DIAPHRAGM.

Often confounded with palpitation of the heart, is generally caused by over-exertion, such as a fast run in the hunting-field; it is also sometimes seen in tetanus. Its most prominent symptom is a convulsive motion or jerking of the whole body, accompanied by a dull, thumping noise, unconnected with the pulsation of the heart, emanating posterior to that organ in the region of the diaphragm. In some instances the impulse of the heart is barely perceptible; the pulse is small and weak, and there is great difficulty in breathing. The spasmodic movements of the diaphragm are not synchronous with the pulse; this, along with the fact that the sound proceeds from parts posterior to the heart, at once points out the difference between this affection and cardiac palpitation.

Treatment.—Generally speaking, a good diffusible stimulant, with warm clothing and quietude, is all that is necessary. Should the symptoms continue, opium is to be administered, and if at any time the dyspnoea be great, and the animal in danger of dying from apnoea, it may be necessary to abstract a moderate quantity of blood in order to relieve undue pulmonary congestion.

RUPTURE OF THE DIAPHRAGM.

Many cases of this lesion are reported by veterinarians. I am afraid, however, that in most of them the rupture has been
mortem, arising from the pressure of the intestines, distended with gases evolved after death. It is stated that the rupture, when occurring during life, is always found in the tendinous portion of the muscle, and that that occurring post mortem is in the fleshy part of it. In nearly every subject brought for dissection, if kept unopened until the abdomen has become much distended, the diaphragm is found ruptured. I am not acquainted with any symptoms diagnostic of this lesion, except those of abdominal pain, distressed breathing, and general disturbance. Mr. Robinson of Greenock tells me, however, of a case in which for two days prior to death there was general uneasiness, pawing with the fore feet, and, what might be looked upon as diagnostic, a dark patch of perspiration was seen to be constantly present on the skin opposite the diaphragm on one side. On making a post mortem a knuckle of intestine was found in the cavity of the thorax, forced through a round aperture in the diaphragm, opposite the patch of perspiration. Beyond this, I can gather no reliable information from the writings of veterinary authors which would justify me in laying down any rules for its recognition. If I were to do so, what I might state would be calculated more to mislead than to enlighten.

Should the lesion be found post mortem in the tendinous portion, or if at any time the gap be stained with extravasated blood, the probabilities are that it occurred during life.
CHAPTER LVI.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(M.) DISEASES OF THE DIGESTIVE ORGANS.

With very rare exceptions, diseases of the digestive apparatus are results of errors in feeding. Some of them have been already discussed under the head of Dietetic Diseases, and need not again be referred to. I may here, however, briefly observe that horses are best kept in health and working condition when fed upon an admixture of food requiring thorough mastication, and that horned cattle are best kept in health when, in addition to the more nutritious aliments, they are freely supplied with food requiring remastication, such as hay, grass, or straw.

Observations on the diseases of digestive organs point to the conclusion that in the horse the intestines are more liable to suffer from disease than the stomach; whilst in the ox and sheep the reverse is the case; and in the dog, consequent upon its power of vomition, the stomach is more rarely disordered than one would be led to expect from the nature of its food, &c.

In the horse the stomach is a simple organ, small in comparison to the size of the animal, and in contrast with the volume of the intestines. It is but slightly called into action during the digestive process, and provided the food be properly masticated and incorporated with the salivary secretions, it is arrested for a short time only in the stomach, but is passed onward into the intestinal canal, where the process of digestion is completed. On this account the intestines are more liable to disease. It is also a remarkable fact that easily digested food, if given over-abundantly, is apt to derange the small intestines, whereas food containing much woody fibre, such as over-ripe hay, more particularly rye-grass, coarse straw, &c., accumulates in the large intestines, and there causes derangement, inflammation, and even paralysis of the intestinal muscular tissue. It is also a fact worthy of notice, that if food be given artificially prepared by boiling or steaming, it is retained in the stomach itself, and if given over-
DISEASES OF THE DIGESTIVE ORGANS.

abundantly, causes distension, inflammation, paralysis, and even rupture. This is accounted for by the circumstance that food imperfectly prepared for intestinal digestion is retained or imprisoned by the action of the pyloric structures, and thus distends the stomach by its bulk, or by gases evolved by the process of fermentation, which is apt to ensue. By bearing these facts in remembrance, the practitioner will to some extent be able to arrive at a correct idea of the seat of gastric or intestinal disease.

The food of the horse contains an abundant quantity of starchy materials, and the process by which these are rendered soluble commences in the mouth, not only by their admixture with the salivary secretions, but by a chemical change, through which the non-soluble starch is converted into dextrine and grape sugar, and made fit for the action of the intestinal, biliary, and gastric secretions, and for absorption by the vessels of the gastric and intestinal walls. For the purpose of performing this process the horse is provided with twenty-four mill-stones, in the form of molar teeth, which have the power of crushing and triturating the hardest food, and of an extensive system of salivary organs, which secrete—most actively during the process of mastication—a fluid which most effectively blends with, and chemically changes, the food thus triturated. On this account we find that, when horses are sufficiently but not over-abundantly fed with dry food of a proper quality, the stomach rarely suffers from disease. An error in the diet, however, or a sudden change from one kind of food to another, not only deranges the stomach, but the intestinal canal as well.

In the ox and sheep, the large and complicated stomach not only digests, but also prepares the food for digestion. For example, ruminating animals eat and swallow the coarsest food very rapidly, and they are provided with a large receptacle for its retention, in which it undergoes maceration and reduction to smaller particles by a slow churning movement in the rumen and reticulum, which facilitates its trituration during the process of rumination and after-solution by the digestive fluids.

Without entering further into a physiological consideration of the process of digestion, it will be seen that the stomach of the ox much more actively participates in the process of digestion than that of the horse, and that it is thus rendered more liable to disorder in its first and second, as well as its third and fourth compartments, than the simple, single stomach of the horse.
CHAPTER LVII.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(N.) DISEASES OF THE STOMACH.

INDIGESTION WITHOUT ENGORGEMENT.

From various causes, such as improper food, the process of dentition, diseases of the teeth causing imperfect mastication, ravenous feeding, the presence of other diseases, debility of the stomach itself resulting from some constitutional predisposition, or from food given at uncertain and rare intervals, a condition of indigestion is induced in the horse. In young animals the same is induced by draughts of cold milk; removal from the dam at too early an age, or, what is commonly the case in some districts, compelling the dam to work shortly after the birth of the offspring, and allowing it to suckle at rare intervals and when the dam is heated.

Symptoms.—In the horse the symptoms are, loss of appetite, or depravity and capriciousness of it, manifested by the animal eating at irregular intervals, or having a desire to eat filth—bulimia—with sourness of the mouth, and usually increased thirst; the animal soon becomes hide-bound, has a dry, scurvy skin, there is irregularity of the bowels, and frequent escape of flatus by the anus. If caused by imperfectly masticated food, such as whole oats or coarse hay, these may be found in the feces. In addition to the above diagnostic symptoms, there may be a dry cough, or irregularity of the pulse, which may be slower or faster than natural; colicky pains may also be present in some cases, occurring more particularly in an hour or two after the animal has partaken of food; whilst in others, fits of
giddiness—megrim—and even paralysis occur, the latter condition being not seldom seen in cattle, and very often in dogs.

In the young the above symptoms are more commonly associated with diarrhoea than in the older animal, in which constipation is generally present. The faeces often resemble the colour of the food: for example, if the horse be fed on dark-coloured hay or clover, the faeces will be dark-coloured also; if, on the contrary, it be fed on oats, the faeces will be light in colour; and in the young animal, when fed on milk, it will often resemble it both in colour and consistence, mixed, however, with large masses of curdled milk, and often very foetid. I have often noticed that when indigestion is induced by clover, the urine is very dark in colour, and deposits a thick, almost brick-coloured sediment. This condition of urine, however, need not cause any apprehension, as it is often seen in the clover-fed animal without any disease being present. The urinary deposit mostly consists of carbonate of lime, the tinge being due to the colouring matter of the food. Indigestion, however, is a fertile source of deposit in the urine, which result from imperfect nutrition of the tissues, or a chemical change in the constituents of the blood-plasma, due to the products being imperfectly prepared, or containing some material unfit for healthy nutrition, as already referred to in the former parts of this work.

_Treatment._—Carefully inquire into the cause, and remove it. If due to the process of dentition, the presence of unshed crowns of the temporary teeth irritating and wounding the mouth, or to any irregularity of the dental apparatus, these must be attended to according to the directions laid down under their several heads. In all instances where such causes are not in operation, even when the cause cannot be traced to the food, it will be necessary to make some alteration in the diet, and to examine the various alimentary matters in order to detect the offending one if possible.

If diarrhoea be not excessive, and the animal thereby much debilitated, it will be advisable to give a mild aperient or a moderate cathartic. To the young animal a dose of castor or linseed oil; to the older, a moderate dose of aloes, combined with a vegetable bitter, ginger, or gentian. After the laxative has operated, I have found that the bicarbonate of soda, with
gentian, or, where the stomach seems much debilitated, aperient, or, where the stomach seems much debilitated, aperient, or, where the stomach seems much debilitated, aperient, or, where the stomach seems much debilitated, ammoniac, to have a most beneficial effect, not only improving the appetite, and removing the acidity—pyrosis or "heartburn"—which is usually present—manifested by a tendency to lick the walls or other cold or alkaline material—but strengthening and improving the gastric apparatus.

It may be here stated that the mineral tonics, particularly the salts of iron, are inadmissible, and generally do harm in the earlier stages of gastric debility, or indigestion, often destroying what little appetite remains, and becoming combined with sulphuretted hydrogen in the intestines, tinging the faeces a black colour—a certain sign in all instances that the iron is not digested or absorbed into the circulation, where alone it can be beneficial, and that it is doing harm. It is very true that even in health large doses of iron salts tinge the faeces, but moderate doses have not this effect to any great extent. In some cases the alkaline-bitter treatment fails in having the desired effect. When this occurs the mineral acids, particularly the nitro-muristic, may prove beneficial. In foals and calves pepsine can be administered, as in all probability the indigestion is due to imperfect secretion of the gastric glands; even in the older animal this is often presumably the case, and more especially when the disorder occurs without apparent cause, the same remedy will prove beneficial. It is almost needless to observe that the dieting of the animal is to be carefully conducted, and that pure air, moderate exercise, and good grooming are essentials to good digestion. Occurring in the winter, if the animal be thickly clothed with hair, clipping will act almost magically, restoring the digestion and appetite, which may have been long impaired, notwithstanding remedies, in the course of a few hours. In the cow, chronic indigestion, as exemplified by recurring tympanitis and other symptoms similar to those observed in the horse, and when not occurring from recognisable external causes or other diseases, is often due to the presence of some foreign body in the rumen or reticulum, removable in some instances by the operation of rumenotomy, hereafter to be described. In all chronic indigestions of the cow this operation is recommendable. I have repeatedly performed it successfully, even where no foreign body has been found, the mere removal of the long-retained food having been sufficient to restore the organ to its
DISEASES OF THE STOMACH.

healthy condition. In young calves, indigestion, associated with convulsive fits, is sometimes due to hair-balls; these after a time become gradually disintegrated by the movements of the stomach, and the symptoms may slowly disappear. In rare instances hair-balls are found in fully grown cattle, and, as in calves, result from the animals licking each other. In calves the symptoms of urgency are often relieved by stimulants, such as the carbonate of ammonia or turpentine; should the indigestion, however, remain for a considerable period, recourse must be had to the operation already referred to. It may be here mentioned that common salt given in the food promotes digestion in all animals. In the dog indigestion is manifested by frequent retchings or vomittings and fester of the breath, and is best treated by a brisk purgative, antacids, and a restricted diet.

INDIGESTION WITH ENGORGEMENT—IMPACTION OF THE STOMACH—PLENALVIA—GASTRIC TYPANITIS—HOVEN.

Distension of the stomach may arise from repletion with solid food, or from the evolution of gases arising from solids or liquids contained within it undergoing the process of fermentation, or disengaged from the gastric walls when the stomach is empty, as occurring in conditions of great prostration.

The causes in the Horse.—Impaction of the stomach results from the ingestion of food too abundant in quantity, or greedily swallowed and imperfectly masticated. In those parts of the country where the cooking of food for horses is a common custom, it is found that deaths from diseases and lesions of the digestive apparatus are very common. From the reasons already hinted at, namely, that it is necessary for the food to undergo not only the process of trituration by the teeth, but that it requires to be chemically altered by combination with the saliva, it will be understood that food prepared in any other way, as cooking by boiling and steaming, is unfit to be acted upon by the stomach, and is consequently retained within it—the animal meanwhile continuing to eat—until its walls become distended, paralyzed, or even ruptured.

Some kinds of food, nutritious in themselves, and theoretically calculated to be proper for the horse, are found practically to be highly dangerous. Wheat, for example, which is highly
nutritious, containing, according to Sir H. Davy, 955 parts of nutritious matter in 1000, is found to be improper, deranging the stomach, causing purgation, laminitis, and death. Barley again has a similar effect, and for these reasons is found to be an improper article of diet.

When, however, from various circumstances, such as damaged crops, it becomes compulsory to cook the food, it is necessary that it be given with the greatest caution, in small quantities, and at intervals. Bran again, so useful an article when combined with other foods, or as an occasional mash, if given in large quantities, is retained undigested, and induces a condition of repletion which often proves fatal. Some kinds of hay, musty or otherwise damaged, or too ripe previous to being cut, barley and foreign straw, are also common causes of impaction; whilst green foods, particularly when animals are first put upon them, or if given too abundantly, not only induce engorgement, but also undergo fermentation in the stomach, and thus induce tympanitis.

In horned cattle and sheep the same conditions are produced, most commonly by damp grasses, turnip-tops, maltcums, clover, &c.; indeed it may be stated that various foods, if given over-abundantly, will cause tympanitis, but none so speedily as green clover.

In horned cattle, tympanitis—botten or blown—arising from retention of food in the rumen, frequently accompanies other diseases. It is wonderful how great a quantity of food is found in the rumen of an animal which has died from a disease which has existed for several days or even weeks. In many instances where an animal suffering from pleuro-pneumonia has not partaken of any solid food for a period extending perhaps over a fortnight, it has been found that the rumen contains several bucketfuls of alimentary matters. The ruminating having been suspended, there has been no true digestion, and the food partaken of prior to the occurrence of the illness has lain, as it were, in a mass in the inert and paralyzed rumen, having a tendency to undergo fermentation, and thus induce tympanitis.

An additional cause of retention in the rumen is found in disease of the salivary glands. Fluorens asserted that from the period of feeding to that of ruminating there is a constant abundant secretion of saliva, which is constantly swallowed; if
this be stopped, the contents of the rumen become hard and unfit for regurgitation. In this way ruminatation is suspended, and tympanitis induced. These observations have been confirmed by Colin, who also found that if the parotid ducts were opened, and the secretion thus prevented from flowing into the mouth, ruminatation became suspended.

The act of vomition, rarely performed by the horse, occurring only as a symptom of a grave lesion or disease, might be easily performed by ruminants; in fact the regurgitation of the food during the act of ruminatation indicates this facility, but vomition itself seldom occurs.

It is not my purpose to enter into a physiological discussion upon this matter, but merely to state that I am of opinion that vomition is rendered difficult in the horse by folds of mucous membrane at the cardiac orifice, and that, if from any cause, such as inordinate distension or rupture of the stomach itself, flaccidity, dilatation, or paralysis of the lower end of the oesophagus—the rugae become unfolded, and the cardiac orifice opened—that vomition can and does occur. The valve of Gult, which is described by some authors as a spiral valve at the cardiac opening of the stomach, has no existence.

The true source of the rarity of the act in ruminants is, I think, satisfactorily pointed out by Mr. J. S. Gangee, and is due to the fact that these animals are nauseated with great difficulty. I have, however, witnessed very forcible vomition in cattle suffering from indigestion, as well as the passive return of food into the mouth, which occurs during the profound coma of parturient apoplexy. Indeed, upon more than one occasion such ingesta have found their way into the trachea and bronchial tubes, and have caused a fatal pneumonia in two or three days after recovery from the parturient disease.

The dog, pig, and cat are easily nauseated by various remedies, and vomit with great facility.

Symptoms in the Ox and Sheep.—Tympanitis is diagnosed by a swelling on the left side, which may appear during the time the animal is feeding, or shortly after; the breathing is difficult and laborious, becoming more so as the gas is generated and as the swelling increases. The oppression of the breathing is manifested by the general appearance of the animal; there is expansion of the nostrils, moaning during the expiratory movement,
eructations, dribbling of saliva from the mouth, and some degree of uneasiness; rumination is suspended; the bowels soon become constipated, and if the tympanitis is extreme, there will be a prominence and wildness of the eye which is characteristic of obstruction to the entrance of air into the lungs.

The moan or grunt, which is heard not only in tympanitis, but in various forms of indigestion, even when unaccompanied by distension, is similar to that of pleuro-pneumonia; and on this account indigestion has been mistaken for pleuro-pneumonia and credit claimed for curing the latter disease when it had no existence. The moan of indigestion is rather more prolonged and resembles a groan more than the grunt of pleuro-pneumonia. The gases evolved have been found to be composed of carburetted hydrogen, sulphuretted hydrogen, carbonic acid, and in some cases carbonic oxide. Unless relieved, the animal will die, either from pressure of the distended stomach upon the diaphragm causing suffocation, or from the absorption of noxious gases into the circulation. In some instances, tympanitis is chronic, and, as already stated, may depend upon the presence of foreign bodies in the rumen.

Treatment.—In very urgent cases, the most effectual treatment is that of puncturing the rumen with a trocar, and allowing the gases to escape through the cannula. The operation is to be performed on the most prominent part of the swelling, and at equal distances from the spine of the ilium, last rib, and transverse processes of the lumbar vertebrae. When the symptoms are not very urgent, tympanitis can be relieved by stimulants and stomachics, such as carbonate of ammonia, turpentine, alcoholic preparations, or the vegetable spices, particularly if given in warm ale. After the symptoms of urgency have been removed, cathartics are to be prescribed, such as salts, with crotan and aromatics, care being taken that the animal be kept upon a restricted diet for some days after recovery. When the tympanitis becomes chronic, stomachic stimulants, particularly nux vomica, are to be prescribed; but if, along with the attention to dieting, they fail to give relief, it may be necessary to open the rumen, when the cause may be detected and removed.

Impaction of the Rumen with Solid Matters.

The symptoms are similar to the above, with the exception
that the swelling, resonant when tapped with the fingers in
tympanitis, is dough-like and pits on pressure. In some
instances I have noticed that the pitting remains for a consi-
derable period after the pressure is removed, indicating that
the coats of the rumen have lost their muscular tonicity, and
that its movement is in abeyance, or entirely lost. I have also
noticed that in such cases medicinal remedies do harm until
the viscus has been to some extent emptied, and that the best
method of doing this is to perform rumenotomy before the powers
of life become exhausted.

The best method of performing this operation is as follows:—
After securing the animal by the nose, with its right side to
the wall, plunge a sharp bistoury into the rumen, commencing
the puncture midway between the last rib and the spine of the
ilium, and from four to five inches from the points of the trans-
verse processes of the lumbar vertebrae, cut downwards until the
wound is large enough to admit the hand.

Some practitioners recommend that a towel or handkerchief
be introduced into the wound, in order to prevent the food fall-
ing into the peritoneal cavity. I find it much better to place
a suture at the lower part of the incision through the lips of the
double wound. When this is done, the contents are to be
removed by the hand; the parts are then to be thoroughly
cleaned; the incision in the stomach to be first stitched up, its
edges being turned inwards, so as to get the peritoneal coat into
apposition. The best material for the sutures is small catgut
or fiddle-string. The external wound may then be closed with a
stronger suture of strong waxed twine, over which a stiff pitch
plaster it to be applied. Cathartics are to be administered,
succeeded by vegetable bitters, more especially nux vomica, and
the animal is to be carefully fed. In less urgent cases, where
the rumen still retains some tone and power of movement,
removal of the impaction is to be effected by cathartics and
stimulants, the best cathartic for this purpose being an admix-
ture of croton, aloes, and sulphate of magnesia, succeeded by
a plentiful supply of fluids, treacle, and an occasional dose of
ginger or ammonia. To restore tone to the rumen when debili-
tated, common salt dissolved in cold water has been recommended.
This can do no harm, and failing other remedies, may be given
in tympanitis and impaction.
IMPACTION OF THE THIRD STOMACH.

Variously termed fardel-bound, vertigo, maw-bound. This is a very popular disease, some writers ascribing every case of constipation to impaction of the omasum, basing their conclusions upon the fact that the contents of this viscus are in a dry and hard condition when examined after death. But seeing that this is its natural state, and that, when animals have died from what appeared to be obstinate constipation, its contents have been found moister than natural, I have arrived at the conclusion that what is supposed to be impaction of the third stomach is in reality an inflammation of the mucous membrane of the true stomach—abomasitis—or true gastric inflammation. I do not mean, however, to state that the third compartment does not participate in the disorders of the others; but, on the contrary, that disease commencing in the rumen, reticulum, or abomasum, soon involves the third compartment. I shall not, therefore, separate the description of this disease from abomasitis.

Professor Dick has published a record of a series of cases in which the symptoms, as described by various authors as being characteristic of impaction of the third stomach, were present to a marked degree; the post mortem examinations of the animals that died, however, revealed that the disease was situated entirely in the fourth compartment.

The causes of inflammation of the true stomach are sudden changes in the condition of the food, or in the food itself. That a change in the condition of the food has an effect in causing disease no one will deny, and that it is capable of inducing gastritis is strongly insisted upon by Professor Dick, who brings the following facts to bear upon his conclusions:—"In 1883, Mr. Hardie, Balbegie, about three miles north of Kirkcaldy, in Fifeshire, turned out twenty-six cattle into some pasture fields. For the first fortnight they were housed in the straw-yard at night, but they were afterwards allowed to remain constantly in the field, and they continued to thrive and were quite healthy till the night of the 10th June. For a considerable time previous to this the weather had been very dry, and the grass almost withered up, or at least it contained much less succulence than is usual at that season.
of the year. During that night a considerable quantity of rain fell, but the weather was mild, and continued so for some days afterwards. On the morning of the 11th one was found dead, and many of the rest unwell, being dull, stupid, and their eyes having a fixed and glassy appearance; the pulse was small, and varying from 80 to 100; the animals had an inclination to press forward with the head against anything that came in their way, but especially in a corner. The post mortem examination proved that the disease arose from inflammation of the true stomach, producing a degree of affection of the brain, similar to stomach staggers in the horse.” The treatment prescribed by Professor Dick, namely, repeated bleedings, even to faintness, and large doses of purgative medicines, given in large quantities of gruel, with cold water frequently applied to the head, proved successful in every instance.

In the gastritis of ruminants a highly disturbed condition of the nervous system is a distinguishing symptom, evidenced either by a high state of delirium, coma, or convulsive fits, indicative of disturbance of the brain proper, or by paralysis of the posterior extremities, when the area of the disturbance is limited to the posterior parts of the spinal cord. Paralysis, convulsions, and coma are also frequently seen in dogs when suffering from gastric affections, and the same may be said, but in a less degree, of the horse.

In addition to the above symptoms, the gastritis of ruminants is characterised by more or less diarrhoea, soon succeeded by an apparent obstinate constipation, which, however, is not due to an obstruction by impacted food, but to cessation of the peristaltic action of the intestines, the contents of the stomachs being found generally more or less fluid after death. In many instances the animal strains violently, and passes both blood and mucus, showing that the inflammation has extended into the intestinal canal, and it is said that a hard swelling may be detected on the right side, arising from distension of the third stomach. In many cases, however, general swelling of the abdomen, tympanitis, supervenes early in the disease, and greatly adds to the animal’s suffering.

The treatment pursued by Professor Dick appears to have been successful, but no one now-a-days would think of pursuing such a heroic course; and, bearing in mind that there is an inflammation of a true mucous membrane, when the fourth
stomach is inflamed, and that the constipation results from loss of function rather than impaction, we will do well to recommend a course of treatment calculated more to modify that inflammation than to overcome the seeming constipation. For this purpose sedatives, such as aconite or belladonna, with antacids—bicarbonate soda or potash—and one or at most two moderate doses of an oleaginous aperient, with an abundant supply of fluids for the animal to drink, fomentations to the abdomen, and enemas, are to be prescribed. This treatment is much more calculated to save life than the indiscriminate use of powerful cathartics and stimulants. I speak advisedly, having witnessed many animals destroyed by the administration of repeated doses of cathartics in order to overcome constipation in this affection, the parties prescribing not being perhaps aware that an inflamed part loses its function, and that before the function and the peristaltic movement of the bowels can be restored the subsidence of the inflammation is essential, and that such inflammation is much more likely to be increased than diminished when the inflamed tissue is irritated by drastic cathartics or other remedies, which are supposed to rouse up the action of the bowels. If passage of the feces is not restored in the course of twenty-four hours after the administration of the aperient, it does not follow that it is necessary to repeat it; time must always be allowed in all inflammatory diseases for the inflammation to subside, and for the weakened or debilitated parts gradually to resume their normal functions. The late Professor Strangeways was very successful in the treatment of this affection. At the commencement he gave a dose of oil, with sedatives, and after the febrile symptoms had to some degree subsided, from eight to twelve ounces of sulphate of magnesia, fifteen grains of quinine, and a few drops of sulphuric acid, ample time being allowed before any additional cathartic was given. It was very seldom necessary to repeat the medicine, as the bowels became gradually restored to their natural healthy condition.

**Impaction of the stomach in the dog and cat are naturally overcome by vomition, which also occurs sometimes in the pig, but should this not occur, an emetic is to be administered.**

The dog suffers from catarrhals inflammation of the stomach—*gastrorrhæa*—induced by improper food, or occasionally by exogenous influences, in which there is a high degree of fever, hot nose, blood-shot eyes, and quick pulse, abdominal pain, constipation.
and frequent or almost constant attempts to vomit, a dense mucus tinged with bile being sometimes thrown up. The most successful treatment consists in allaying the gastric irritation by small doses of hydrocyanic acid and antacids, and when this is effected, gently moving the bowels by a small dose of castor oil. Enemas may, however, be beneficially employed in the earlier stages, and if the abdomen be tender or swollen, fomentations or a warm bath. If the strength seem to fail, the pulse small, &c., stimulants are to be cautiously given. As a rule, however, they do more harm than good, and if the first dose is not succeeded by visible improvement they are to be discontinued.

SYMPTOMS OF GASTRIC IMPACTION IN THE HORSE.

Pawing with the fore feet, especially the near one, eructations of gas, sometimes attempts at vomiting, with occasional discharge of saliva from the mouth, some degree of fulness of the abdomen, colicky pains, tremors of the superficial muscles, particularly those in the region of the left shoulder, with partial sweats upon the body, are more particularly the symptoms of this disease.

True gastritis, except from the action of direct irritants, such as poisons, is but seldom seen in the horse; its stomach may be distended even to rupture, without any marks of inflammation being discoverable after death.

When inflammation of the stomach is induced by arsenious acid, the symptoms are great pain with uneasiness, the animal alternatingly getting up and lying down, tympanitic abdomen, faces mixed with mucus, the saliva foetid, and its secretion increased, mouth hot, extremities cold, nausea, purging, and great prostration of strength with delirium. When the irritation is caused by the bichloride of mercury, there is, in addition to the above symptoms, a profuse discharge of saliva from the mouth. The antidotes for arsenical poisons are the hydrated sesquioxide of iron, chalk, albumen, or magnesia, and for the mercury salt, white of eggs, the symptoms of irritation being combatted by opium, oleaginous purgatives, and demulcents.

TREATMENT OF IMPACTION OF THE STOMACH IN THE HORSE.

Alcoholic purgatives; if combined with tympanitis, oil, turpentine, or ammonia; enemas, fomentations to the abdomen; care
at all times being taken that the animal be prevented from throwing itself suddenly down and causing a fatal lesion, namely—Rupture of the Stomach.

RUPTURE OF THE STOMACH.

The symptoms are, sudden tremors, particularly of the fore extremities; in many cases extension of the near fore limb, profuse perspiration, great prostration of strength; the animal breathes heavily, staggers in its walk, looks round to the flanks, and is generally seized with symptoms of vomiting, during which the head is suddenly depressed, the nose brought down to the sternum by spasmodic contractions of the inferior cervical muscles, and in many cases there occurs an actual expulsion of food from both the mouth and nostrils.

The value of vomition as a diagnostic symptom of rupture of the stomach is certainly very great. Occurring in rupture of the stomach, it is said to be due to the muscular coat having first given way, thus allowing the mucous membrane to protrude, and the rugae of the cardiac orifice to become unfolded. This conclusion is true in part only, for vomition will occur in rupture of the colon or other intestine, and in dilatation of the oesophagus. It must, however, be admitted that the act of vomition is much more complete in rupture of the stomach and dilatation of the cardiac orifice than it is in any intestinal lesion. The differential symptoms of rupture of the stomach, which occurs in the great curvature towards its pyloric portion, and a paralyzed condition of the cardiac orifice, are chiefly those manifested by the general condition of the animal. In rupture, prostration and rapid sinking of the animal powers are very extreme, the pulse feeble and fluttering, and death soon closes the scene; whilst in the other condition, though sweats bedew the body, and the animal exhibits extreme agony, the vital powers still remain tolerably strong; the pulse, though frequent, still retains some fulness, and the surface of the body and extremities are never deathly cold as in rupture.

Abdominal pain, as ordinarily manifested by rolling, striking violently at the belly, &c., is not a constant symptom of rupture. In some cases the animal will stand immovable, breathing heavily, being seemingly afraid to perform any movement which may increase its anguish; in other instances, the ordinary symptoms of abdominal pain, combined even with delirium, are present.
I have observed that all medicinal remedies increase the severity of the symptoms. This is undoubtedly due to their escaping into the peritoneal cavity. Mr. Percivall asks the questions—Can vomiting take place after rupture? Will the real stomach retain any power of ejection? Would ejection of the contents upwards be produced by the abdominal muscles and diaphragm without the aid of the stomach? And replies, "I should very much doubt it. I should rather feel inclined to the opinion that the act of vomiting should be taken as a proof of the entireness of the stomach. At all events," he says, "we may have rupture happen without vomiting; and, consequently, we must cease to regard that symptom as pathognomonic, though we may justly consider it, in company with others, as one throwing much light upon the nature of the case. Our guides, in the absence of any one infallible pathognomonic sign, must be—the history of the case, the subject of it, the circumstances attending it, the inflated or enlarged condition of the abdomen, the symptoms of colic or gripes ceasing and becoming succeeded by cold sweats and tremors, the pulse, from being quick and small and thready, growing still more frequent, and at length running down and becoming altogether imperceptible; the countenance denoting gloom and despondency of the heaviest character, with or without vomiting."

This graphic description contains some errors. For example, the enlargement of the abdomen is not generally associated with rupture; on the contrary, the belly in some instances is smaller than natural, the abdominal muscles being rigid and tense from tonic spasm, and the condition of rupture is undoubtedly associated with vomiting, for it not unfrequently happens that the animal dies immediately after that act.

In addition to impaction from over-feeding, the stomachs of old horses particularly become ruptured from degeneration of their walls. When this occurs the gastric walls are exceedingly thin, and atrophied for some distance around the breach; and if examined microscopically the tissues are found to have lost their histological character, being reduced to a granular debri or an oily material.

There is no treatment for this lesion; and if the veterinary surgeon is satisfied that it has occurred, he will do well to order the animal to be put out of its misery.
CHAPTER LVIII
SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(0) DISEASES OF THE BOWELS.

CONSTIPATION.

The bowels of some horses are naturally torpid. Constipation, however, may be looked upon more as a symptom than as a disease in itself. So long as the animal remains in health there is no necessity to employ active remedies for the removal of constipation, and all that is necessary is to give an occasional bran or linseed mash. Should the condition be caused by the nature of the food, such food must be changed, and one of a more laxative description substituted.

In many diseases constipation results from debility of the bowels, and is to be overcome by remedies, the action of which on the healthy body may be considered astringent in virtue of their tonic effects, such as the salts of iron, cinchona bark, gentian, nux vomica, and other tonics and bitters.

Constipation may also arise from paralysis of some portion of the intestines, and if large and repeated doses of cathartics be administered, a fatal termination may be looked for, either from their toxic effects upon the system generally, or their direct irritation on the intestinal canal. It is, therefore, advisable to act cautiously in all cases of constipation, to allow plenty of time for the paralyzed bowel to regain its tone, to rouse it by stimulants and nervine tonics, and to administer enemas, which may contain turpentine. One symptom of paralysis of the bowels is diagnostic, namely, the absence of intestinal murmurs. Another may be mentioned of not infrequent occurrence,
especially if the paralysis be in the large intestines, namely, a
dilated, dry, and non-contractile condition of the rectum, which
seems, when the hand is introduced, as a large cavity with
passive walls.

COLIC.

Colic is of two kinds, namely, 1st. Spasmodic; and 2d. Flatulent.

Spasmodic Colic.—A spasmodic contraction of the muscular
coats of the intestines, which may run on to inflammation, due
to improper food, sudden changes of diet, exhaustion from over-
work, particularly if associated with long fasting, and to other cir-
cumstances, trivial in themselves, and quite insufficient as causes
if uncombined with other disturbing influences. For example, a
drink of cold water is often supposed to cause colic. Now
water, no matter how abundantly it might be drank, as is
witnessed in diabetes, does not cause colic; but if an animal
be exhausted by a long journey, or bathed in profuse perspi-
sration, even a moderate quantity of cold water will then cause
disturbance and abdominal pain.

Colicky pains are also symptomatic of intestinal concretions,
parasites, intussusception, mesenteric abscesses, and of diseases
of other organs, such as the pleura, kidneys, liver, &c. On this
account colic has been divided by some authors into true and
false; the true including the colicky pains arising from all
intestinal diseases involving structural change, and the false
those from other causes.

Amongst other causes of colicky pains may be enumerated
mesenteric abscesses, succeeding strangles or other suppurative
disease, ulcers in the stomach, the irritation of numerous para-
sites, cancer, and chronic inflammation and thickening of the
intestinal walls.

I have seen two cases of chronic induration of the duodenum
and pylorus. The symptoms in both were as follows:—
Capricious appetite, slight colicky pains succeeding in about
two hours after a meal, a peculiar staring appearance of the eye,
hanging back in the stall to the full length of the collar shank,
a peculiar frightened look, irregularity of the heart’s action, the
pulse sometimes slower, sometimes faster than natural, but
always irregular; gradual emaciation and death. The post
mortem appearances, a thickening of the submucous areolar
tissue, which presents a whitish and fibrous character, and being united most intimately with the mucous and muscular coats, which were both pale, thickened, and contained much translucent material. The whole mass was firm, and resisted the knife.

**Symptoms.**—When colic is truly intestinal the symptoms are, sudden pain, pawing, kicking at the belly, looking round at the flanks, lying down, rolling, struggling in a variety of ways, or lying outstretched; then suddenly rising, shaking the body, and remaining for a short period free from pain. After a short interval, however, the symptoms return, sometimes in an aggravated, occasionally in a modified form, and this occurs again and again, until the animal is either relieved or dies from enteritis, pain, and exhaustion. During the paroxysms of pain the breathing is accelerated, sighing, or panting, the pulse is observed to rise in frequency, and to become more or less full and hard; during the intervals of ease, however, it falls to its normal condition. At the commencement of the attack there is generally a frequent evacuation of small quantities of feces, which are sometimes hard, sometimes soft; the urine is passed in small quantities, or there are frequent but ineffectual attempts to micturate; and if an examination be made **per rectum**, the bladder will very often be found full and distended, the urine being retained by a firm contraction of its neck. In some instances, more especially if the animal has been fed on moist grasses, potatoes, or unripe corn, there is diarrhoea and escape of much fetid flatus.

The seat of the spasm is sometimes in the small, often in the large intestines; the symptoms during life, however, do not enable us to ascertain this with certainty. I have, however, observed that pawing with the fore feet, frequently looking round to the side, with very acute and sudden pains, point to the small intestines as being the seat of the spasm. In some instances there has been violent agony, a tendency to rear, and to kick savagely with one hind foot, when the disease has been confined to the small intestines, whilst a disposition to back or press the hind quarters against a wall or other solid object is almost a constant symptom of impaction of the colon.

**Flatulent colic,** whether occurring primarily or subsequent to an attack of spasmodic, is a condition from which much more serious results are to be apprehended than the spasmodic.

Its causes are—weakness of digestion, but most commonly
food which easily undergoes fermentation, such as raw potatoes, green clover, a mixture of maltcums and brewer’s grains, wheat, and boiled food.

In this form of colic the expression of pain, though not so acute, is much more constant than in the spasmodic form; the abdomen is more or less tensely swollen, and resonant upon percussion; the pulse soon becomes rapid and feeble, the breathing difficult and mostly thoracic, the extremities become cold, there is more or less delirium, the animal reels to and fro; twitching of the muscles, retraction of the lips, and if relief be not afforded, death ensues either from asphyxia, blood poisoning from absorption of gases, or rupture of some portion of the intestines. When the animal lies down or rolls it is observed that it performs these acts much more carefully than when suffering from spasm.

Tympanitis may arise independently of any cognizable extrinsic cause. Occurring during the progress of another disease, it is always to be looked upon as indicative of a very grave condition, that the animal powers are so exhausted as to be bordering upon dissolution, and becoming amenable to chemical laws. Tympanitis also occurs in obstructions of the intestinal canal from calculi, tumours, or other mechanical causes, and generally indicates the approach of death.

Treatment.—Spasmodic Colic.—To Mr. Gamgee is due the credit of having advocated, against much opposition, the most rational and successful treatment introduced into this country. Mr. Gamgee reasoned that pain and spasm were but symptoms of the presence of an irritant in the intestinal canal, and that the removal of this would be succeeded by disappearance of the symptoms. A long and successful experience enables me to confirm Mr. Gamgee’s conclusions that colic is to be treated by cathartics and enemas.

The best form of administering the cathartic is that of a ball, containing from five to ten drachms of aloe, depending upon the size of the animal and the nature of its food. If the food be of a succulent nature, a moderate dose may be given, but if it be dry, such as the rye-grass hay of Scotland, the larger quantity is to be administered; the enemas, consisting of warm water only, should be repeatedly administered—the enema-funnel answers the purpose very well. The same writer condemns all opiates
and stimulants. There are many circumstances, however, which go to prove that this condemnation is not always justifiable, and that when the symptoms of pain are extremely urgent, it becomes an absolute necessity to relieve them by opiates. For this purpose I find nothing superior to tincture of opium in two to three ounce doses mixed with warm water, or the hypodermic injection of morphia may be substituted for the tincture of opium; hot fomentations to the abdomen, with friction, are also serviceable.

If the attack be a very slight one, a single dose of the opiate will often give permanent relief. There is one thing that I should warn the practitioner about, and that is, no certain dependence can be placed upon this, and that in all cases where the animal cannot be watched for some time afterwards the purgative is not to be omitted; and upon no account a horse attacked late at night, and thus relieved, is to be left without the cathartic being administered, for it has often happened that when all are asleep in bed the pains have returned, and the horse in the morning found dying or dead.

One favourable sign of the subsidence of colic is free urination; it shows that the spasm of the neck of the bladder has subsided in sympathy with the subsidence of that within the intestine.

The condition of the bladder must be carefully examined in cases of colic, and if found distended, the urine is to be withdrawn by the catheter.

Flatulent Colic.—In addition to the administration of the cathartic for the removal of the cause, it becomes essentially necessary that the symptoms of urgency be promptly relieved, and for this purpose agents which neutralise, combine with, or dissipate the gases are to be freely administered; and my experience is that there are none superior to ammonia, turpentine, and linseed oil. The neutralising agents, such as the chlorate of potash, animal charcoal, &c., are of little or no use whatever. The French veterinarians recommend puncturing the colon, and state, if this be done early, and before the animal has become exhausted, that the operation is successful, that it not only liberates accumulated gases, but stimulates the peristaltic action of the intestinal canal, and that shortly after the introduction of the trocar and cannula there is an escape of flatus and discharge of feces from the anus; this result being supposed
to be due to some electric or galvanic action of the metal upon the intestinal walls. The operation has not, however, found much favour in this country, those who have performed it having found it to afford no relief. I performed it on two occasions, and although the cases terminated fatally, some relief was afforded and life prolonged; the animals, however, were in a state of great prostration. If the operation is to be successful at all it must be performed early. The large intestines of the horse may be easily punctured from any part of the floor and inferior aspect of the abdomen. If the cannula or tube, however, become blocked up with fecal matters, these should be removed by a long probe, in order that the gases may escape freely. One of my late students, Mr. Gunn, of Beauty, has repeatedly performed the operation of puncturing the intestines in colic with complete success, and has invented a special trocar and cannula for the purpose. It is made by Arnold and Sons.

**Impaction of the Colon.**

As already stated, animals over-abundantly fed, or kept upon food containing much woody fibre, are liable to suffer from the accumulation of such matters in the colon and caecum. The diagnostic characters of this, in addition to symptoms of general abdominal pain, are a tendency to push backwards, to press the tail against any solid object, to resist by violent straining the introduction of the hand and enemas into the rectum. In some cases the hard and impacted mass may be felt by the hand, introduced into the rectum, and there is also some enlargement or distension of the abdomen. The propriety of administering cathartics by the mouth for the relief of this condition is a question of very great importance, for it has often happened that rupture of the colon has occurred in the course of some hours—generally about twenty—after the administration of an aloetic ball, the condition of the intestinal canal, when examined post mortem, having been found as follows:—The stomach and small intestines more or less emptied of alimentary matters, or containing large quantities of fluid; the large intestines distended with a mass of more or less hardened material, or partly hard and partly soft; the mucous membrane sometimes highly congested, sometimes pallid, but
ruptured, and the contents more or less escaped, as in ruptured stomach, into the peritoneal cavity. I have repeatedly witnessed this, and the question has arisen in my mind whether the rupture has not been induced by the contents of the small intestines having been forced into the already over-burdened large ones by the action of the purgative. Concluding that this was the case, I have injected aloetic solutions into the rectum, and endeavoured to excite the commencement of purgation in the large intestines. In some instances this has succeeded, whilst in others it has failed; the failure has been due to the expulsion of the medicine by the animal. I have found it the best method to dissolve two ounces of aloes in a pint of hot water, and to administer it with a syringe having a long flexible tube, at a temperature of about 90° F. If this be retained for an hour or two, it generally has some effect, but if immediately expelled, it ought to be repeated. I am well aware that writers on materia medica will say that the specific action of aloes is limited to the large intestines and rectum, no matter how it gains entrance into the economy, and that this result will be obtained by its administration by the mouth. My experience leads me to the conclusion that, although it may irritate the posterior bowel during its exit from the body, its primary effect is to stimulate the peristaltic action and glandular secretion of that part of the intestines with which it first comes in contact.

Rupture of the colon from impaction, or when resulting from degeneration of its muscular coat, is manifested by symptoms similar to those of rupture of the stomach. If occurring from impaction, it will be found that the passage of enemas, which had previously been difficult, owing to the violent straining or resistance of the animal, becomes suddenly easy; the hand introduced into the rectum meets with little or no resistance, the intestine itself being dilated and paralyzed.

The condition of degeneration observable in the stomach and colon is sometimes met with in the rectum, causing a gradually decreasing contractile power of the bowel, in consequence of which the fecal matters accumulate to an inordinate extent, and are only expelled by violent straining and contraction of the abdominal muscles. In such instances, it is observed that the feces of the horse, which in its normal condition is divided into globular pellets, is discharged from the body as a huge
mass, resembling a large German sausage, and as thick as a man's leg. I have observed this condition, which may be denominated paralysis of the rectum, as a result of injury of the spine or sacro-lumbar nerves, and independently of injury in old horses habitually kept upon coarse, indigestible food. When resulting from injury, it has sometimes disappeared, either spontaneously, as the lesion which caused it became repaired, or by the assistance of nervous tonics, more particularly nux vomica, and blisters to the sacro-lumbar region. In many instances, it has been necessary to empty the bowel by the hand four or five times daily, and to administer enemas to prevent pain and colicky symptoms. Rupture of the rectum has sometimes occurred from this cause.

Rupture of the rectum has also occurred within my experience from the formation of an aneurism of the haemorrhoidal arteries, the pressure of the aneurismatic tumour having caused atrophy, not only of the muscular and peritoneal, but also of the mucous coat of the intestine, and rupture of these being caused by some sudden effort; haemorrhage has occurred both into the intestinal canal and peritoneal cavity. Rupture has also been witnessed as a result of cancer, and as an accident during parturition.

Accidental rupture of the rectum, posterior to its peritoneal lining, is not necessarily fatal; but if anterior to the termination of the peritoneum, the escape of faecal matters and of blood into the peritoneal cavity will cause death. In one case, where the rectum was pierced by the foot of the foal during parturition, causing a recto-vesical fistula, I was enabled to bring the lips of the wound together by metallic suture, and induce their ultimate union, the mare eventually doing well.

Inversion of the rectum is caused by violent straining during parturition, or attempts to expel faecal matters; as a result of paralysis; in the coma and spinal paralysis witnessed in parturient apoplexy in the cow; and in pigs it is a common occurrence owing to constipation. In dogs it results from the impaction of bones or other hard bodies in the bowel, causing violent straining. Its reduction in all animals must be preceded by thoroughly emptying the bowel of all sources of irritation. When this is effected, the bowel, thoroughly washed and oiled, is to be carefully returned into its proper position,
and retained there by a suture across the anus, or a rope or truss properly adjusted, and the sense of pain and irritation soothed by opium. For several days the bowel is to be carefully emptied by the hand, or enemas, and the animal fed upon a restricted diet. Purgatives are to be avoided; the bowel may, however, be lubricated with oleaginous enemas.

In recurring inversion, which commonly happens in the pig, excision of the protruded intestine may be successfully performed; and in all cases where it is found impossible to return the bowel, the engorged mucous membrane is to be carefully dissected from the subadjacent structures, and a reduction thus effected. It now and then happens that the sphincter of the anus closes firmly, forming a constricted neck, preventing the return of blood to such an extent that the protruded intestine speedily becomes gangrenous. If the sufferings of the animal be not very great, it is generally advisable to allow a short time to elapse before removing the sphacelated mass, in order that new adhesions may form; but if the animal suffers severely, it is advisable to insert sutures for the purpose of causing union between the gut and anal opening, and at once remove the whole protruded mass with a sharp bistoury, the subsequent pain and straining being alleviated by a full dose of opium. When several feet of the intestine are protruded, as sometimes happens after parturition, it becomes an impossibility to return it. The intestine is generally lacerated from being trodden upon, and humanity renders it necessary that the animal should be put out of its sufferings.

HAEMORRHOIDS OR PILES.

With the exception of the dog, the domestic animals rarely suffer from piles, which consist at first of congestion of the mucous membrane at the verge of the anus, and subsequently of dilatation of the haemorrhoidal veins, constituting small tumours. These sometimes protrude outside the anus, and bleed frequently. The diagnostic symptoms of piles are switching of the tail, and a tendency to rub it against the wall; pain during the act of defecation, and the faeces being tinged with blood. The dog sits on its haunches and pulls itself along in that position. The examination of the anus will reveal the
presence of vascular tumours, and of much congestion and swelling of the mucous membrane and skin.

_Treatment._—The cause of haemorrhoids depends upon some obstruction to the portal circulation, constipation, and frequently on retention of hardened faeces in the rectum; the treatment must therefore be directed to the removal of these by manipulation, gentle laxatives, and a restricted diet. The uneasiness may be modified by fomentations, enemas, and the application of some mild astringent. Astringent ointments are also useful, more particularly an ointment consisting of equal parts of oak galls and hog's lard; the benzoate of zine ointment is also a useful application.

**Imperforate Anus.**

A congenital malformation met with in all the domesticated animals, particularly in the pig. It gives rise to symptoms of colic, and generally proves fatal shortly after birth. In some instances the anal opening is well formed, but the rectum at a short distance from it forms a "cul de sac," which is not continuous with the alimentary canal. In other instances the anal opening is permanently closed by skin, the bowel terminating in a pouch underneath it. When this condition is met with, relief is possible by puncturing the intestine, thus forming an artificial anus.
CHAPTER LIX.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(O) DISEASES OF THE BOWELS—continued.

INFLAMMATORY DISEASES OF THE INTESTINES—ENTERITIS.

Enteritis, or inflammation of the bowels, may safely be stated to be the most rapidly fatal inflammatory disease to which the horse is liable, destroying life in the course of a few hours. Indeed, it is very doubtful whether the disease recognised as enteritis by veterinarians is a true inflammation at all, as its course and progress, rapid termination, and post mortem appearances tend to confirm the opinion that it partakes more of the nature of apoplexy than of inflammation. It is very true that impaction, constipation, intestusception, the presence of calculi, or the action of irritant poisons, may cause great congestion and inflammation of the intestinal membranes; but the disease to be described originates sui generis, and very often without the occurrence of an immediate and recognisable cause of direct irritation. This fact has led some practitioners of very great experience, amongst whom may be mentioned the late Mr. Lawson of Manchester, to arrive at the conclusion that enteritis never originates in colic, spasmodic or flatulent. Many writers assert that enteritis is situated in the small intestines, more particularly in the ileum and jejunum. My experience, however, leads me to the conclusion that it is more commonly situated in the cæcum and colon than in any other part of the intestinal canal, but no portion of the tube is exempt. The only recognisable causes are, over-fatigue, cold
from exposure, or from washing with very cold water whilst the animal is heated, and thereafter inadequately clothed.

PATHOLOGY.

Various writers state that the inflammation is situated in the muscular coat. This is evidently a mistake, as the congestion is of the greatest severity in the mucous membrane, the redness of which is of a deep venous colour, approaching to blackness, in patches of various extent, and associated in many cases with extravasation of blood into the canal. Of course, when such extreme congestion of the mucous membrane exists, all the coats are more or less implicated, but the primary and gravest condition is limited to the mucous membrane.

The submucous tissue is generally much thickened; there is loss of cohesion, the mucous membrane being easily stripped from its attachments; some effusion of serum into the intestinal canal, causing purging in cattle and dogs; but in the horse purging seldom or never occurs, though the contents of the bowels may be found fluid after death. This seeming constipation results from paralysis or loss of function, and is marked by complete retention of the fecal matter. In some rare instances enteritis may terminate favourably in the horse; but in the great majority of cases mortification results, or the animal dies from the debilitating effects of hemorrhage into the intestinal canal, or from prostration of the nervous system induced by pain. Gangrene may result in eight or ten hours, the animal rapidly succumbing. In some instances, however, death may not result for several days. In one instance a horse lived for a period of five days, the bowel being found sphacelated, the process of ulceration having commenced at the edges of the gangrenous patch. It is very rarely that ulceration occurs in the horse, but it may be witnessed both in cattle and dogs.

SYMPTOMS.

The first noticeable signs are those of abdominal pain; generally, however, they are preceded by some degree of constitutional disturbance, rigors, accelerated breathing, repeated evacuations of small quantities of feces, and general depression;
the mucous membranes soon become deeply congested, the mouth dry, the tongue contracted, and now and then of a brownish colour; the appetite of course being lost; the pulse is hard, wiry, and quick; the belly is tender upon pressure; the abdominal muscles more or less contracted; and if tympanitis be absent the belly may seem tucked up and smaller than natural. By-and-by the symptoms of dulness and depression give place to those of excitement and pain; the horse stamps the ground with the feet, strikes at the belly, lies down, but much more carefully than in spasmodic colic, or makes feints to do so; it may roll upon its back; turns its eyes anxiously towards the flanks, pants, blows, and sweats with pain. There are no sharp paroxysms of pain with intervals of ease as in colic, but the pain is constant, distressful, and agonizing; in some cases so much so, that the sufferer seems afraid to express it, except by a most anxious expression, which is a characteristic and diagnostic symptom. Now and then the animal will stand persistently with the head in a corner, and paw the ground for hours together with one or both fore feet alternately. The pulse is hard, wiry, and quick, often ranging from 80 to 120 beats per minute; and as the disease advances, it becomes thready and imperceptible; the animal sighs, or even groans with pain; the perspiration runs off the body; the skin is never dry, at one time hot, at another cold; the countenance becomes haggard, the eyes expressive of delirium, pupils dilated. The horse may throw itself about in a most dangerous manner, or walk round its box incessantly; then it will stand, balance itself, its legs give way, when it may fall and die after a few convulsive struggles, or suddenly all symptoms of pain may subside; it will then stand quiet, and even drink or endeavour to feed; its breathing becoming more or less tranquillized; but the haggard expression of the face still remains; the pulse continues thready and imperceptible; cold sweats bedew the body; the belly becomes tympanitic; gangrene has now set in; it trembles incessantly; the legs and ears are deathly cold; the mouth cold; the breath cold, and even fetid; the lips drop pendulous; the eyes become more amaurotic, and after a varying interval death closes the scene, the bowels remaining inactive to the last. If, however, in three or four hours from the commencement of attack there be some abatement of the symptoms; if the surface of the body
become dry, if there be a passage of flatus or faces, the pulse becoming fuller and softer, and the characteristic anxiety leave the expression, a favourable termination may be anticipated. This, however, is rarely the case.

**TREATMENT.**

Concluding that the constipation which is so prominent a symptom in enteritis is due to obstruction from alimentary matters, veterinarians generally administer powerful cathartics. It has, however, been shown quite conclusively that it is always dangerous to propel fecal matters through an inflamed portion of bowel; and that in most cases the effort is useless, so far as exciting peristaltic action in the inflamed portion is concerned. Purgatives, however, stimulate and excite the muscular and excretory action of the healthy intestines anterior to the inflamed part; the result of this is, that the inflamed part becomes more and more distended, inflammation is increased, the blood-vessels become ruptured; it becomes softened, and its vitality is ultimately destroyed. It is therefore a fact that the inflamed part, the function of which is lost, consequent upon the inflammation, affords an impediment, and that purgatives, as a rule, have no true purgative effect—that is to say, they do not cause the discharge of fecal matters by the anus.

Two great principles are therefore recognised, namely—first, to relieve pain, and, second, to arrest as far as possible all movement of the intestines; and for these purposes opium is to be administered in large doses. For the horse, one, two, or even four drachms of the powder may be administered, succeeded by smaller quantities at short intervals, or by the subcutaneous injection of morphia (the solution of the meconate of morphia being recommended); or an ounce of the extract of belladonna may be administered, succeeded, if necessary, in six hours by smaller, two-drachm, doses. In addition, hot fomentations to the abdomen are useful; and they should be continuously applied for at least an hour at a time. Enemas of warm water may also be gently administered; they are not, however, to be repeated too often, and if at any time they increase the pain they should be discontinued.

If, after the abatement of the active symptoms, the bowels remain torpid (as they generally do), the practitioner is by no
means to attempt the removal of this torpidity by the admi-
istration of cathartics or aperients of any kind; for if the animal
is to recover, it must be dependent upon the restoration of
function and tone to the inflamed bowel; and it is well known
that for this end perfect quietude of the inflamed part must be
maintained.

The advisability of bleeding in enteritis will depend entirely
upon the condition of the animal. If the pulse be moderately
full, if depression be absent, an abstraction of blood commen-
surate with the strength of the vital powers will be followed
generally by abatement of the symptoms, and if performed
early is beneficial. Should the appetite return, great care must
be taken that the food be of the simplest and of the most easily
digestible kind, such as scalded bran and boiled linseed given
in moderate quantities; the eating of dry food being prevented
by a muzzle. Care must also be taken, when the functions of the
bowels are restored, that no undue accumulation of fecal matters
be allowed to remain in the rectum. The question of adminis-
tering stimulants during the acute stage will also greatly depend
upon the condition of the animal; they usually do more harm
than good, but if tympanitis be present, one or two doses may
be tried. If they give relief they may be continued, but if on
the contrary, they aggravate the pain or seem to have no effect
they are to be discontinued.
CHAPTER LX.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(D) DISEASES OF THE BOWELS—continued.

INTUSSUSCEPTION AND VOLVULUS.

INTUSSUSCEPTION (from intus, within, and suscipio, to receive), and volvulus (from volvo, to roll up), a twisted bowel. Under these names various forms of entanglement of the intestines have been described, giving rise to abdominal pain, enteritis, and death.

INTUSSUSCEPTION.

By intussusception is meant the prolapse or slipping of a portion of intestine into the cavity of that immediately posterior to it. In consequence of this the natural course of the intestines is interrupted by a kind of knot, consisting of three successive portions of bowel; the immediate effect of which is obstruction to the passage of the intestinal contents, and to the return of blood from the imprisoned portions of intestine involved, along with which some portion of the mesentery must be included.

Both the small and large intestines are subject to it in all the domesticated animals. When occurring in the large intestine, the cæcum caput coli is that usually involved, and instances have occurred, both in horses and cattle, of recovery after sloughing of the invaginated cæcum. Within my own experience, a cow treated by me, after seven days of obstinate obstruction of the bowels, expelled the gangrenous portion, measuring several inches in diameter, and the animal recovered. Mr.
Aitken, V.S., Dalkeith, has a case on record of a cow which recovered after five days of illness, the gangrenous portion being expelled with the feces. Before recovery from intussusception can occur, it is necessary that the opposed peritoneal surfaces become adherent, and the imprisoned portion separated by ulceration.

Invagination of the small intestines, owing to the severity of the inflammation, is necessarily fatal.

**Symptoms.**—In the cow already mentioned, the symptoms were those of enteritis and obstinate constipation. The treatment consisted in the administration of opium. In Mr. Aitken's case drastic cathartics were administered from the commencement. The symptoms in the horse, as related by the late Mr. John Field, are as follows:—"Pain; restlessness, in some cases approaching to madness, unrestrainable; wandering about; rolling on the back; sweating, in some cases profuse; crouching; sitting on the hind quarters, almost diagnostic; anxious countenance; frequent feeble pulse; belly at first of natural size, subsequently fuller, in some cases distended, dependent upon the locality of the intussusception; membranes, in advanced stage, turgid, injected; mouth moist and clean, or furred and offensive; respiration accelerated; continued restlessness; rearing with fore legs into manger, and standing upon that point d'appui, looking back from side to side; extremities cold; pain absent, tranquil; sighing or snorting; death. The sighing may exist in some cases and not in others, and in some retching and vomiting."

I am, however, of opinion that there is no diagnostic symptom of volvulus, intussusception, calculus, or strangulation of the intestines in the horse; that the above symptoms are common to all, characteristic of none. In the dog and pig, however, vomiting of stercoorous matters is generally witnessed; but even in these animals this symptom may be induced by any cause of obstruction. Stones accidentally swallowed, pieces of bone arrested in the small intestines, are frequent sources of obstruction in the dog.

**Treatment.**—It has been proposed to cut down upon and mechanically remove the source of mischief. I think, however, that the operation would be as bad as the lesion. If intussusception be due to contraction of one portion of intestine, and the slipping in of that contracted portion into the healthy portion
behind, remedies calculated to relieve spasm may prevent its occurrence, but cannot overcome it when once established.

**VOLVULUS, OR TWISTED BOWEL.**

This may occur in either the small or large intestines. Several cases are reported of such occurrences in the various veterinary journals. They, as well as strangulation from the entanglement of the intestines by pedunculated tumours, are, however, very rare, and have no diagnostic symptoms during life beyond what have already been pointed out, and are necessarily fatal. Mr. Percivall's *Hippopathology* may be consulted with advantage on this matter.
CHAPTER LXL

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(0.) DISEASES OF THE BOWELS—continued.

INTESTINAL CONCRETIONS.

The common seat of the various concretions is found to be in the large intestines, where they sometimes attain a large size, and as much as twenty-five pounds or more in weight. Occasionally, but very rarely, they have been found in the stomach weighing four or five pounds.

They were studied by the late Professor Morton, and classified under three heads, namely, 1st. Phosphatic calculi; 2d. Out-hair calculi; and 3d. Mixed calculi.

1st. Phosphatic Calculi.—These are hard, smooth, and polished on their external surface, bearing much resemblance to a common pebble. If a section be made of a phosphatic calculus, it will be found to consist of concentric layers arranged around a nucleus, generally consisting of a piece of iron or stone. If several of them, or any other form of calculus, be formed together, they are generally flattened upon their sides, or concave on one side and convex on the other, the convexity of one stone fitting into the concavity of another, and so on. This form of calculus is now much more rarely met with than formerly. This arises from the circumstance that the food of animals is much better prepared and cleaner than it used to be, and containing, therefore, fewer accidental materials or foreign bodies, which formed the nuclei.

Their chemical composition, according to Girardin, is as follows:—
Ammonio-phosphate of magnesia, 48:00
Phosphate of lime, 19:00
Water, 14:00
Animal matter, 0:80
Soluble salts, &c. 6:60
Extractive matters, 4:00
Fatty matters, 7:00
Loss, 0:60

100:00

From the above analysis it would be seen that the calculi contained some animal matters; in fact the earthy materials are glued together by mucus, &c.

Their occurrence is accounted for as follows by Professor Morton:—"In the cereal plants, certain of the phosphates are met with, and in considerable quantities. It is then to this food that we are to look for their origin, coupled with a morbid state of the digestive functions, by which it does not undergo the necessary change, probably from the gastric juice not being sufficiently powerful to dissolve these phosphates. A foreign body being accidentally taken into the stomach, which may be a nail, or anything else, as a piece of stone, serves as a common centre, the phosphates arrange themselves in their turn, and in doing so they blunt that which by its sharpness would wound the lining membrane of the organ. If from its magnitude the calculus is unable to pass through the pylorus, the stomach becomes its residence. They will give rise to colicky pains, depravity of appetite, perhaps to wind-sucking or crib-biting, and in the end will invariably, by accumulation, destroy the life of the horse.

2d. Oat-hair calculi, generally found in the caecum or colon, consist almost entirely of the beard of oats, barley, or other grain. They sometimes attain a large size, but are light in comparison with the first-named. They, however, assume the same shape, and are occasionally mixed with phosphatic salts.

3d. The mixed calculi are composed of phosphatic salts, fecal matters, oat-hair, or any indigestible matter which may accumulate in the intestine.

In addition to these, food may adhere to the mucoereal membrane, constituting what is termed a stercoral concretion, con-
sisting very often of straw-knots, &c., firmly glued together. This will sometimes be found perforated through its centre, as to admit the passage of faeces.

The presence of these concretions at some time or another constitutes a fatal obstruction. Many symptoms are laid down as being diagnostic of calculus, such as sitting on the haunches, lying upon the back, &c. I am not, however, aware that there is any diagnostic sign, beyond those of violent abdominal pain as an obstruction, by which they may be discovered during life; as they can only be guessed at by recurrent attacks of colic or constipation. In one case which fell under my notice there were no symptoms of abdominal pain, but merely constipation which nothing could overcome. For two days after the animal had been observed to be off its food the pulse remained natural on the third day, however, the abdomen became tympanitic, the pulse rose rapidly, and the animal died; and the post mortem revealed the presence of a phosphatic calculus, about ten pounds in weight, firmly lodged in the single colon. In one case examination per rectum enabled me to feel and remove a calculus from the rectum, the animal being immediately relieved. This shows the necessity of such an examination in all cases of abdominal pain.

Cases are recorded of polypi or other tumours in the stomach and in the intestines. Gastric polypi finally plug up the pyloric orifice, and give rise to fatal distension.

To prove the fallacy of foreseeing the action of the bowels in cases of mere constipation, and to show how long a horse may live without passing any faeces, I may mention that I had a horse under my care that had no action of the bowels whatever for twenty-five days, yet it made a good recovery. It was noticed that after a purgative had been administered the pulse became greatly accelerated, mucous membranes injected, and that it manifested signs of pain, which continued for several hours, in fact until the medicine was excreted by other organs. Except when suffering from the effects of medicine it ate a moderate quantity of food. Another case lived eighteen days, passing no faeces, and showing no pain except when irritated by purgatives; towards the end of that day it showed pain, and died from calculus in the single colon. Upon this point the following letter from a late student, Mr. Martin, now in London, is instructive:—
DISEASES OF THE BOWELS.

"London, 6th June 1879.

"My dear Sir,—In reply to your note you kindly sent me of 29th ult. in reference to the case of stoppage of the bowels of a horse I had under my care, I have now to inform you that he died on Monday evening, May 26, it being the thirtieth day that no feces had passed from him. Within six hours of his death he started blowing, suffering a deal of pain, abdomen distended very much. Next morning, on post mortem examination, I found the bowels gorged, and a calculus firmly fixed in the single colon, weighing 2½ pounds, 5 inches in diameter. All the other parts were perfectly healthy. It appeared to me that the bowels becoming so full, caused him to die sooner than he would have done had less solid food been given him, although the result would have been the same."
CHAPTER LXII.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(0.) DISEASES OF THE BOWELS—continued.

DIARRHOEA.

This term is applied to all cases of simple purging in which the feces are loose, liquid, and frequently discharged without any coexistent inflammation. Diarrhoea may be a spontaneous effort to discharge from the intestines something which is obnoxious to them or to the system generally. It is also induced by a variety of causes in all animals, such as indigestible food; sudden changes of diet, particularly from a dry to a moist one; medicinal substances; parasites; derangement of the liver; or copious draughts of water when the animal is heated.

Some animals are particularly prone to diarrhoea from trivial causes; narrow-joined, flat-sided, and loosely coupled horses—that is to say, horses in which the space between the ilium and last rib is large—and those which are of a nervous temperament, are apt to purge without apparent cause. They are vulgarly called "washy" horses. Such horses will start upon a journey in the best of apparent health, but before they have proceeded any great distance, will commence to purge more or less freely. They are hard to keep in condition, and require the best of food. If, however, put to slow work they will sometimes do well enough.

SYMPTOMS.

The symptoms of diarrhoea are purging, the fecal matter being semi-fluid, of a dirty-brown colour, without offensive odour.
or clay-coloured and fetid. If the condition continues long, the animal loses flesh, the appetite fails, and in some cases ascites, or even farcy and glanders, may supervene.

TREATMENT.

When the purging arises from the presence of some offending matter in the intestinal canal, its expulsion must be aided—and this applies to all our patients—by a moderate dose of castor or linseed oil, and the diet must be changed. Purging in the dog is often induced by a too exclusively farinaceous diet, and it is impossible to arrest it without an entire change of food. If the purging arises from no apparent cause, or if the bowels do not regain their normal condition after the action of the aperient has subsided, it will be necessary to administer calmatives, such as opium or mild astringents, such as chalk; proceeding, however, very cautiously, as too sudden a check may induce complications of a grave character. Boiled starch or flour gruel may be allowed the animal to drink; the food must be of the sweetest and best kind, and given in moderate quantities.

If there be much fever the sulphite or hyposulphite of soda may be very advantageously given dissolved in the drink, or mixed with the food. If the animal be depressed and weak, moderate and repeated doses of the spirits of nitrous ether will afford relief, and promote the restoration of the bowels to their natural condition. Should this treatment prove futile, the more powerful astringents, such as catechu or kino, or, what has proved more successful with me, the oil of turpentine and opium beaten up with eggs, are to be administered. Some practitioners recommend the mineral acids, such as the aromatic sulphuric acid, these remedies having a tonic as well as an astringent action upon the bowels. Warm clothing and perfect quietude are necessary.
CHAPTER LXIII.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(O) DISEASES OF THE BOWELS—continued.

SUPERPURGATION.

Although a form of diarrhoea, from its gravity, and the important legal questions it may give rise to, superpurgation deserves a separate consideration. It is well described by the late Mr. Haycock. He says—"Superpurgation, or over-excitement of the intestines from the undue action of purgative medicine, is a condition of the bowels which the veterinary surgeon is frequently called upon to treat. The symptoms associated with the action of a purgative upon the bowels are quickened rate of the pulse, attended with a partial but temporary loss of its force; the breathing also is a little hurried. This is the most conspicuous when purging is about to commence, and the animal is nauseated. If the purging, however, does not go on to an undue extent, these symptoms soon subside, the pulse becomes normal, and the nausea succeeded by a desire on the part of the animal for food; but should the animal be of weak constitution, or be taken out of the stable and ridden or driven a considerable distance while the purging continues, or taken out too soon after what is called the 'setting' of the physic, or if the purgative does be too powerful in the first instance, or if two or more of these circumstances or causes act in association, the purging will in all probability become excessive, and the life of the animal may be placed in danger. Purging may continue for a long time; but so long as the patient is kept quiet in the stable, so long as the appetite remains good, and the pulse maintains its regular, slow, and round beat, little or no danger need be apprehended;
but if the appetite fail, if the pulse becomes thready, and the patient weak, it behoves the owner to act with promptness."

"The following symptoms," says that excellent observer John Field, "indicate the violent and too long-continued action of purgatives, and invariably portend a fatal termination:—Staring glassy eyes; frequent, indistinct, feeble, and sometimes thread-like pulse; purging offensive matters, with or without distension of abdomen, or distended abdomen without evacuations; offensive mouth; tongue pallid or whitish with fur, and pasty; smell quite peculiar; respiration tranquil, but it becomes laborious when the belly becomes enormously distended; extremities warm; the horse usually stands still, sometimes paws or wanders about, and but rarely lies down."

Superpurgation does not always depend upon the strength of the dose. In some instances as little as four drachms of aloes have been succeeded by fatal consequences. Again, horses in an obese condition, and those suffering from slight colds, are easily acted upon by purgative medicines, and are apt to sink from superpurgation. A full dose of aloes, from six to eight drachms, operating quickly, is seldom succeeded in healthy animals by any evil consequences; the same quantity, however, if divided into two or more doses, has a much more depressing effect, and is apt to be followed by serious consequences. In the first instance, the quantity, by its strength, insures its own expulsion; whilst in the second, the aloes is absorbed into the circulation, excites a toxic effect upon the system generally, and reduces the horse to such a state of debility that its succumbs to the purgative influence. The explanation of the tendency to superpurgation in the horse is to be found in the fact that its bowels are extremely vascular in comparison with those of other animals, and that the effect of the purgative acting upon so vascular a surface is grave and serious. I have already pointed out that many young horses, when first brought into the stable, are rendered susceptible to various diseases by the debilitating influences of indiscriminate purging, and that such a method of treatment is uncalled for and irrational. In addition to the symptoms described by Messrs. Haycock and Field, I have observed that those of laminitis are induced by purgatives, and that when they occur they indicate a condition of great gravity.

The post mortem appearances are those of congestion of the
intestinal mucous membrane generally, concentrated in many cases in that of the cæcum caput coli; a thick, tarry appearance of the blood, and extreme blackness, congestion, or apoplexy of the lungs, the blood being, as it were, deprived of its watery elements, altered in its composition, rendered too viscid to circulate through the pulmonary capillaries, and so altered chemically as to be rendered unfit for perfect oxidation.

In order to prevent the occurrence of superpurgation after the administration of an aloetic, or, more particularly, a mercurial and aloetic purgative, it is necessary that the practitioner should order the animal to be fed on an easily digestible diet, such as warm bran mashes; that the quantity of water should be restricted, and that the chill be taken off it, for nothing is so apt to induce inordinate intestinal action as large quantities of cold water whilst the animal is in physic. It is also necessary that no green food, roots, or other articles of diet, containing much water, and laxative in themselves, should be allowed at this period. If a purgative does not seem to take effect in from twenty to twenty-four hours after its administration, moderate walking exercise is to be prescribed; for it is a fact that the longer a purgative is retained in the body, the greater the danger from its superaction; if, however, purging has actually commenced, exercise, by increasing it, is apt to cause harm. It is therefore necessary to keep the horse quiet until the physic has “set.”

TREATMENT.

So long as the horse remains moderately lively, the pulse but slightly accelerated, the countenance natural, and so long as some appetite remains, it is unnecessary to take any active measures to restrain the purging, which is the natural and physiological response of the intestines to the action of the cathartic; it is therefore irrational and dangerous to check it, and all that is requisite is to allow the horse to partake of demulcent drinks, such as thin flour gruel, if it will do so spontaneously, at the same time keeping it perfectly still, warmly clad, and taking care that it does not drink too freely of anything whatever. Should there be any colicky pains, moderate doses of opium are to be administered. Care, however, must be taken that the purging be not checked even by these means too
suddenly; as the consequence of this would be congestion of
the intestinal mucous membrane, denoted by tympanitis, great
prostration, cessation of the purging, and the other symptoms
described by Mr. Field, finally terminating in death.

If the purgation continue, an endeavour should be made to
overcome it gradually but not too quickly. For this purpose I
know of nothing better than tincture of opium, chalk, and flour
gruel. Two ounces of the tincture are to be given, with the same
quantity of prepared chalk, mixed with a quart of flour gruel,
every three or four hours until the purging is checked, but appli-
cations being in the meanwhile applied to the abdomen, great
care being taken that the animal has no access to cold water or
other fluid, as its thirst is great and it is apt to drink inordin-
ately; but it is essential that it should have small quantities
of flour gruel or other emollient drink, not only to allay the
painful and feverish thirst, but to keep the blood in a proper
fluid condition to circulate through the minute pulmonary capil-
laries. If the prostration be very great, stimulants, as wine or
brandy, are to be tried; if they seem to act beneficially, they
are to be continued, but not otherwise.

As a medico-legal question, the occurrence of superpurgation
after the administration of a simple and moderate cathartic by
the veterinarian is one of great importance. In no case where
due caution has been taken, where the dose has not been more
than the necessities of the case required, and where the above
mode of after treatment has been enjoined, should the veteri-
narian be held responsible.

Superpurgation is typical of inflammatory diarrhoea, no matter
what its cause may be, and as the symptoms and treatment are
identical, there is no necessity for further description. It may,
however, be mentioned that a form of diarrhoea, even more fatal
in its consequences, accompanied by a greater degree of prostra-
tion, and terminating fatally in a shorter period of time than
that induced by medicinal cathartics, is brought about by
an over-abundant feeding upon raw potatoes. Again, the
same condition is induced by the ingestion of food containing
sand, small pebbles, or other materials incapable of being
digested. There is no cause, however, so rapidly fatal as
raw potatoes, the toxic properties peculiar to the natural order
"solanaceae" being seemingly exerted upon the system gene-
rally, in addition to the irritating effects of the tuber itself upon
the intestinal canal.

The treatment of inflammatory or acute diarrhoea when arising
from these causes becomes a matter of extreme delicacy. For,
in the first place, the retention of the irritating material in the
intestinal canal is a source of danger in itself; and, secondly,
the extreme purgation which it induces is no less a cause of
fatal termination. It therefore follows that the practitioner, on
the one hand, must take care not to check the efforts of nature
to expel the offending materials from the body too suddenly by
the administration of powerful astringent remedies; and, on the
other hand, that he should endeavour to modify the violent purgative and irritating effects by the administration of demulcents,
calmatives, such as opium, and antacids, such as the bicarbonate
of soda; and to support the animal's strength by diffusible
stimulants, such as the ethers, wine, and alcoholic stimulants,
in moderate and oft-repeated quantities; fomentations to the
abdomen, and other means calculated to allay irritation and
febrile disturbance, being by no means neglected.
CHAPTER LXIV.
SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(0.) DISEASES OF THE BOWELS—continued.

DYSENTERY.

Whilst superpurage and acute diarrhoea most commonly attack the horse, chronic diarrhoea and dysentery are much more commonly seen in cattle, dogs, &c. Dysentery, sometimes termed "colitis," or "bloody flux," consists of an inflammation having a tendency to terminate in ulceration of the mucous membrane and glandular structures of the large and sometimes the small intestines. Dysentery is observed both in an acute and chronic form; the chronic in horned cattle being often dependent upon the scrofulous diathesis, with tubercular deposit and ulceration of the intestinal glands.

CAUSES.

Except as a concomitant of other diseases, such as rinderpest, or when induced by direct irritants, acute dysentery is a rare form of disease. It may, however, be induced both in horses and cattle by bad food or putrid water; some kinds of pastures, especially those situated upon moorlands and in shady places; on this account it was called "moor-ill" and "wood-evil" by the old writers. Occasionally it is seen as a complication of "red water" and "parturient peritonitis."

In the dog it is witnessed as the effect of cold and damp, and in the intestinal form of distemper.

SYMPTOMS.

In the ox the acute form is attended with shivering fits, variable temperature of the body, arching of the back, and increased sensibility or tenderness of the loins; a furry tongue, and clammy mouth. The animal grunts, yawns, grinds its
teeth, and at short intervals discharges a quantity of this excrementitious material, mixed with pellets of hardened feces and blood. There is much straining, and irritation of the rectum and anus, which appear sore and red; some abdominal pain, evinced by arching of the back, whisking and extension of the tail, associated with tympanitis, great dulness, thirst, rapid emaciation, and an aphthous condition of the mouth.

In the chronic form there is great emaciation, a verminous condition of the skin, looseness of the teeth, and anasarcaous swellings of the intermaxillary space; the feces become deeply tinged with blood, contain much mucus, and after a time an admixture of fetid purulent matter. Ulceration about the anus ultimately appears; the feces are discharged involuntarily: the eyes soon become dim and sunk into the orbit, and the animal dies.

Both in diarrhoea and in dysentery of a chronic nature the feces contain gaseous materials, which cause the appearance of little air bubbles upon their surface when discharged from the body. The urine of an animal suffering from dysentery is of a high colour, increased specific gravity, containing an inordinate quantity of urea, proving the rapidity of the tissue changes occurring within the economy.

TREATMENT.

Both in the acute and chronic form much benefit is to be expected from the administration of a mild oleaginous aperient, succeeded by opium and antacids. Should these not succeed, styptics, as the oil of turpentine, or astringents, as tannic acid, sulphate of copper, perchloride of iron, or alum; and to overcome the factor of the feces, hyposulphite of soda, or other deodorizers, may be given with advantage. When the disease is essentially chronic, associated with much emaciation and a tubercular diathesis, cod liver oil in such doses as the animal will tolerate up to four ounces, given twice a day, mixed with four or five eggs, will prove advantageous. It must be remembered, however, that all treatment must be subservient to careful dieting; cake, good hay, and other articles easy of digestion and nutritive, being at all times recommendable. For the dog the same agents, in doses proportionate to the size of the animal, along with proper diet, such as rice-milk or flour porridge, are to be prescribed.
CHAPTER LXV.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(O.) DISEASES OF THE BOWELS—continued.

ASCITES, OR DROPSY OF THE ABDOMEN.

Peritonitis, or acute inflammation of the coats of the abdominal cavity, having been already described in *Principles and Practice of Veterinary Surgery*, I need only refer to it here as a condition which may lead to an alteration of the peritoneal structure by the inflammation becoming chronic, and to a collection of fluid in the cavity, constituting ascites, which may be defined to be a collection of fluid in the peritoneal sac—the nature of such fluid being sometimes simple, consisting of a pale straw-coloured serum, sometimes more complex, the serosity being mixed with flakes of lymph, and inclosed in cysts or cavities by the adhesions of false membranes.

CAUSES.

Direct disease of the peritoneum is a very rare cause of ascites in all the domesticated animals except the ox, in which it is found frequently, as a result of scrofulous growths—"grapes"—studded over the surface of the membrane.

Ascites results most frequently from diseases of the liver, the heart, or the portal blood-vessels; as a consequence of cardiac debility in some exhausting diseases; and from the ingestion of improper food, as when animals are kept during winter upon poor, ill-drained, or moorland pasture. It may also arise from anaemia and deficiency of albumen in the blood, whether induced by parasites, as in the "rot" in sheep, or independently
of such invasion from any cause inducing deficiency of albumen in the blood. In sheep and lambs a sanguineous form of ascites is not rarely met with, variously termed red water, water braxy, and "maladic rouge," or diarrhemia, by the French. In this latter condition, not only is there a transudation of the fluid of the blood, but also of the colouring material (see Purpura), the globules being sometimes dissolved, sometimes entire, and more or less altered in appearance in the serosity. Ascites is also witnessed as a complication in hydrothorax and dropsy of the pericardium.

In the dog, dropsy of the belly is generally caused by disease of the liver, induced by over-feeding and want of exercise.

SYMPTOMS.

These are denoted by enlargement of the belly, sheath, and sometimes the legs, the enlargement being due to effusion, as indicated by fluctuation, and a dull sound on percussion. As the fluid increases, the breathing becomes thoracic; and in the sheep and ox edema of the submaxillary areolar tissue and inferior cervical region, with emaciation, feeble pulse, irregularity of the bowels, looseness of the hair and wool, and other symptoms common to exhausting diseases, supervene.

TREATMENT.

When arising from a removeable cause—as improper food—an improvement in the health and a disappearance of the collected serosity may be effected by generous diet, occasional aperients, and by tonics, more particularly the salts of iron. When associated with deficiency of albumen in the blood, it may be useful to introduce albumen into the economy by administering eggs to those in which the appetite is absent, and to those which still eat, by feeding on oil-cake and other nutritious diets, the effect of common salt as an aid to healthy digestion not being lost sight of. When ascites is due to organic diseases of the liver, heart, or other organ, treatment is of no use, except to palliate the symptoms, and in all cases it is better to put the animal out of its suffering. Paracentesis abdominis, or tapping, gives temporary, but seldom permanent relief.
CHAPTER LXVI.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(P.) DISEASES OF THE LIVER.

Diseases of the liver are rare in the domestic animals, with the exception of sheep, which are destroyed sometimes in great numbers by various diseases of the liver, induced by exclusive feeding upon turnips, particularly Swedish turnips, causing a fatty or degenerative condition of the organ; by stimulating food, long continued, such as the various cakes, inducing congestions and softening, and by the invasions of the "distoma" or fluke worms, giving rise to the disease termed "the rot," or of "strongyles," which appear as small bladders throughout the organ, and cause anaemia and death. But neither the horse, ox, nor dog is exempt from hepatic affections.

CONGESTION OF THE LIVER.

Under this head three forms are included, namely—1st. Passive congestion of the hepatic and portal veins, arising from anything which interferes with the circulation of the blood, such as disease of the heart. In my paper on Traumatic Pericarditis, published in the Veterinarian in 1857, I pointed out the co-existence of this condition of the liver. Its occurrence is explained as follows:—In heart diseases there is stagnation of blood in the vena cavae and hepatic veins; in time, as explained by Frerichs, this is propagated to the portal vein, and to the organs from which it takes its origin; the liver then becomes turgid with blood, and the congestion extends to all the veins of the digestive system. In the same manner consolidation of
the lungs, by arresting the circulation of the blood, causes con-
gestion of the liver and enteric veins, and is one cause of the
diarrhea which is so often an accompaniment.

The second form of congestion is that termed "active," in
which the arterial capillaries are mostly involved. This form is
induced by food of a stimulating nature, given over-abundantly,
particularly during hot weather, or when the animal is not
receiving sufficient exercise. It has been already pointed out
that animals rapidly get up for sale frequently suffer from a
diseased condition of the liver. Dr. William Budd points out
how congestions of the liver occur so commonly in the human
being; the same reasons are applicable to some extent to the
lower animals, particularly as hepatic congestions are generally
met with in over-fed, slowly worked, pampered horses, such as
those belonging to brewers, or people whose business requires
animals for show as well as for labour. He says—"Amid the
continual excesses at table of persons in the upper and middle
classes of society, an immense variety of noxious matters find
their way into the portal blood that should never be present in
it, and the mischief which this is calculated to produce is en-
hanced by indolent or sedentary habits. The consequence often
is that the liver becomes habitually gorged. The same or even
worse effects result in the lower classes of our larger towns from
the inordinate consumption of gin and porter." Compared to
its frequency in man, active congestion in the lower animals is
exceedingly rare. The late Professor Coleman was of opinion
that this rarity was due to the simplicity of the liver in the
horse—having no gall bladder—compared to its complicated
structure in man. This view is evidently erroneous, as the
livers of other domesticated animals are furnished with gall
bladders, and it cannot be said that they are more liable than
the horse to hepatic congestions, except from errors in feeding,
to which they are perhaps more frequently exposed. Hutrel
d'Arboval takes another view, and describes the exemption from
disease to be due to the little areolar tissue entering into the
composition of the horse's liver; this view is evidently as
erroneous as that of Coleman.

Symptoms.—In hepatic congestions, as proved by post mortem
examinations of animals which have died from "ramollissement,"
or softening, with perhaps rupture of both liver and its capsule,
DISEASES OF THE LIVER.

693

traces of repeated attacks of congestion, indicated by various differences in colour and in the consistence of the hepatic textures, are not unfrequently present without there having been any manifestation of symptoms during life, beyond occasional loss of appetite, and perhaps a little dulness. Now and then, however, the following symptoms are observables.—Abdominal pain, the animal looking to the right side; yellowness of the mucous membrane; high brownish colour of the urine; constipation of the bowels; the faeces sometimes of a clay colour and fetid, with a sour, acid, or even offensive condition of the mouth; grinding of the teeth; a desire to eat earthy substances, or lick the walls; and in very rare instances pain, manifested by lameness in the off (right) shoulder, with varying degrees of febrile disturbance.

Treatment.—Bearing in mind that the engorgement may become so excessive as to cause rupture of both gland and capsule, practitioners must abstract such a quantity of blood as the character and nature of the pulse will warrant; so long as the artery is round, the pulsation distinct—no matter how severe the seeming dejection and debility may be—a free abstraction of blood will be succeeded by amelioration of the symptoms, as they are but consequences of the state of hyperæmia, the removal of which being of paramount importance.

With regard to medicine, cathartics, followed by neutral salts, as the sulphate of magnesia, cause a drain from the portal system, and thus relieve the congestion. In the dog, elaterium has a special effect, by causing watery stools. A recurrence of the congestion is to be prevented by a restricted diet and regular exercise.

The third form of congestion is that due to engorgement with bile, arising from obstruction, parasites in the ducts, or inflammation of their mucous membrane, by which their calibre becomes diminished, and the flow of bile consequently arrested. This condition is associated with epizootic diseases, and is termed by some veterinarians "bilious influenza," and is characterised by yellowness of the visible mucous membranes and high coloured urine, with the symptoms of the epizootic from which the animals suffer.

The treatment of this form calls for no special comment, except that the administration of the so-called liver stimulants, as
calomel, is contra-indicated, for the reason that the secretory powers of the gland are not interfered with, but that it is incapable of discharging the secreted bile, owing to the tumidity or swollen condition of the lining membrane of the small bile ducts; salines and a non-stimulating diet are therefore indicated.

**HEPATITIS, OR INFLAMMATION OF THE LIVER.**

Hepatitis, or inflammation of the liver, is one of the rarest diseases affecting our domesticated animals, the majority of cases diagnosed as such being probably due to congestion. It sometimes, however, occurs, and cases are recorded where the post mortem examination has revealed the presence of abscesses transformed exudates, and even ossification of the products of inflammation.

The inflammation may have its seat in Glisson's capsule, when it is called "perihepatitis," and examinations of old horses slaughtered for dissection point out the fact that this form of inflammation—the formation of false membranes, and the adhesion of the liver to the diaphragm—is of no rare occurrence, unaccompanied, however, with any symptoms during life which point to its presence. Even in the human being, perihepatitis is rarely accompanied by serious derangement, unless the inflammation extends to the portal or hepatic veins, or causes obstruction of the larger bile ducts—events of rare occurrence.

—(FERRICHS.) In all probability this inflammation of Glisson's capsule accompanies the pleurisies to which the horse is so particularly liable.

Hepatitis, or inflammation of the glandular structure, may occur in a circumscribed or in a diffused form; the circumscribed leading on to suppuration—as in cases mentioned by the late Mr. John Field and others—or to the formation of patches of fibrous tissue, which appear as firm, light-coloured spots scattered throughout the organ; whilst the diffused form induces rapid degeneration of the glandular structure, with softening and atrophy of the organ, or an indurated condition of it.

In the primary stage of the acute diffused form, patches of hyperæmia occur, the peripheral portions of the lobules being filled with a more or less fluid exudate. The viscus is swollen in proportion to the number and size of the inflammatory patches;
the parenchyma is loosened and lacerable. As the inflammation advances, the red colour fades, and is replaced by a brownish or greyish-red tint in some parts, and yellowish-red or pale yellow in others. This condition, as well indeed as nearly all morbid conditions of the liver, is often accompanied by a similar state of the kidneys, and sometimes of the spleen.

_Causes._—The causes are similar to those of congestion. "In hot countries hepatitis assumes an epizootic form, especially about the end of summer. It is almost always connected with inflammation of the other abdominal organs. After death the liver is found congested, of a greyish-red colour, and weighing from forty to fifty pounds. In addition to ordinary symptoms, there is irritation of the skin. Lessona describes such an epizootic as having occurred in Italy in 1827."—(GAMGER.)

_Symptoms._—The animal is dull, inactive, has a heavy head, lustreless eye, and loathes its food. Mr. Percivall says, "the horse seems as if it was suffering some inward pain; but it is clearly not of an acute kind. It has not lain down during the past night; its dung-balls are small and dark-coloured; its urinary discharges scanty; and there is manifestly a strong fever arising in the system. The fever runs on, and commonly on the second or third day after its onset turns out to be what farriers call 'the yellows'—known by them to be so from the remarkable circumstance of the mouth and eyes assuming that colour. The inner surfaces of the lips and cheeks, the tongue, the conjunctivae, and in some cases the transparent cornea and iris as well, turn yellow, manifesting the diffusion of bile over the body; and the same is further demonstrated by the deep golden dye of the serum of the blood. I have also observed yellow matters floating about in the aqueous humor. The dung-balls are deeply imbued with bile, and in some cases enveloped in a viscid, bilious, mucous matter as well; their colour is that of a reddish-brown, leaving when rubbed upon white paper much the same stain as opium would. If any urine be caught, it will be found to be thick, to exhibit the same bilious tinge, and to deposit, on standing, a copious lateritious sediment. The horse will probably lie down quiet, and yet not appear easy, but from time to time turn a dolorous look at its side, and soon after raise itself up again; and if the right side be pressed against it will flinch, or bite, or otherwise express tenderness there." In
addition to the above symptoms, lameness in the off shoulder has been observed. My own experience leads me to conclude that this is a rare symptom, and is more particularly symptomatic of the existence of abscesses or of foreign bodies in the gland. In one case a thorn has been discovered; in other two, which came under my immediate observation, a stocking needle was found in one, whilst in the other a calcified exudate, surrounded by purulent material, was detected after death. In the latter case, the symptoms of liver disease, which had continued for many months, became associated with those of chronic tetanus, and, finally, with ascites. I think it right to mention that in another animal which had died suddenly, in addition to a calcareous concretion, rupture of the liver was found, the animal having manifested no symptoms of disease during life.

_Treatment._—In the earlier stages of acute hepatitis, purgatives and sedatives, more particularly aconite, or, if the symptoms be very acute, nauseants, as digitalis or veratrum. In human practice, ipecacuanha stands in high repute. It is given in large doses for the purpose of causing nausea, profuse diaphoresis, and frequent bilious motions. Its value in the treatment of the liver diseases of horses and cattle has been proved to be very great, and it is almost invaluable for the dog and other carnivora. It will be clearly understood that calomel and other so-called liver stimulants are inadmissible in this condition; if, however, the liver remain sluggish after the subsidence of the febrile symptoms, one or two doses may be given in combination with stomachics.

**CHRONIC HEPATITIS.**

This form of disease may occur as a sequel to or independent of acute hepatitis.

It tends to create various changes in the substance of the liver, whereby it either becomes enlarged and softened in structure, or hardened, indurated, and diminished in bulk.

Induration of the liver is described under a variety of names—cirrhosis, interstitial hepatitis, hob-nailed or gin-drinker's liver, nutmeg liver, and chronic atrophy; and the nature of the changes which occur in the liver substance are explained in three ways:—

(1.) Dr. Goodeve, who takes the view of Dr. Budd, says that
DISEASES OF THE LIVER.

"when it commences with inflammation or congestion, the course which leads to atrophy is as follows:—Fibrinous exudation takes place; this occupies the portal canals, and extends even into their minute ramifications, so that the very lobules may be separated by the exudation. Livers in this early stage are much enlarged, are firm and tough—sometimes very tough—the external surface, perhaps, merely uneven, with commencing granulations, and the capsule more or less thickened and opaque. On section there is found considerable vascularity, an amorphous, albuminous exudation, tailed or spindle-shaped cells and fibrocellular tissue separating the lobules. In more advanced stages the fibrous tissue is more decidedly developed. Subsequent to the organization of the exudation, contraction follows, with constriction of the vessels lying in the course of the new tissue, impediment to the circulation in the small branches of the portal veins, starvation and wasting of the tissue by them."—(See REYNOLDS' System of Medicine, vol. iii. page 345.)

(2.) According to this view it is supposed that the fibrous tissue is hypertrophied and condensed, rather by a degenerative action than by one which can be termed inflammatory. Dr. Handfield Jones says—"The change seems to be of a similar kind to that which produces cartilaginous induration of the capsule of the spleen, stiffening of the valves of the heart, and contraction of its orifices, which can scarcely be regarded as an inflammatory origin. We are confirmed in this view by having often observed various minor degrees of condensation and thickening of the Glissonian sheaths, in cases where there was no trace of inflammatory action, as well as by a circumstance which has hitherto been quite unexplained—that is, that the spleen, albeit exposed to the backward pressure of the blood, retarded in the splenic vein, does not become distended in the way that one would expect, but is often, on the contrary, small and soft. In such spleens we have often observed very many of the nuclei throwing out fibres, which is certainly not the natural metamorphosis; and hence it seems not improbable that in this way, owing to increase of fibrous tissue in its substance, the parenchyma of the spleen is less distensible than usual, and has a contrary tendency to shrink and collapse."

(3.) Cirrhosis is attributable to degeneration of the secreting tissue, independently of inflammation, arising from an unsuitable
pabulum passing through the liver, causing a smaller demand for and diminished afflux of portal blood, wasting and absorption of the lobular structure, leaving masses of the connective tissue, which waste less rapidly than the secreting ones; this change being similar to atrophy, as it occurs in muscular tissue, and due to similar causes, namely, imperfection in the quality and diminution in the quantity of the blood.

The cases to be immediately described support this latter view, and that in all probability the atrophic change may also be partly due to the liver not being called upon to perform its function, owing to the animals having been kept in a state of semi-starvation. The cases referred to are as follows:—In the month of January 1873 Mr. James C. Dixon, veterinary surgeon, Rothbury, Northumberland, forwarded a sample of urine from a mare, requesting my opinion as to the nature of her disease. After duly examining the urine, I expressed an opinion that the animal was suffering from some affection of the liver, and wrote for a description of the symptoms. Mr. Dixon replied that he saw the mare on the 7th December 1872; it was then dull, hanging its head, and off its feed; the breathing slightly accelerated; the pulse eighty, small and feeble, but there was no cough; the breath was rather fetid; the bowels regular. In the course of a few days the pulse was down to forty-four, and it was much improved, the bowels regular; but at this time Mr. Dixon ceased visiting it. Shortly afterwards he was told that it drank too much water, and passed large quantities of urine. An examination of the food showed that both the hay and corn were very mouldy and bad. By this time it had lost much flesh, and was "awfully tuck'd up" in the flanks. The eyes were quite yellow, the faeces light coloured, glazed, and having a very offensive smell; the urine of a deep amber tint, and passed in great quantities. It continued alternately better and worse for some time, but losing much flesh. Mr. Dixon says, "I never saw an animal lose condition so fast in my life, except cattle when in the advanced stages of red water. After death," Mr. Dixon says, "the liver seemed dyed with bile. I have seen grocers have coarse paper the colour of this liver." A portion of this liver was sent to me, and found to be identical in appearance with the indurated liver of the human being. Externally the organ was more or less roughened in
DISEASES OF THE LIVER

some places, firm to the touch, and broke down under the finger less readily than natural; in fact was firm, dry, tough, and fibrous, and on section the lobules were in parts completely replaced by a white fibrous tissue, and in others surrounded by an increased quantity of the same structure, giving to the cut surface a mottled granular appearance similar to that presented in the interior of a nutmeg.

Fig. 32.—Cirrhosis of the Liver.

The white parts consist of white fibrous tissue surrounding the atrophied gland structures, slightly magnified.

The kidneys of the same animal were in a stage of degeneration.

Two other animals died on the same farm, namely, a mare and a six months' foal, between the time mentioned and the 25th of March, from liver and kidney disease. The symptoms and appearance of the mare are described by Mr. Dixon as follows:—

"The owner says that for ten days or so before it left off feeding it was very dull, and took a deal of driving. It left off feeding on a Thursday, and I was sent for on the following Saturday, when it presented the following appearance and symptoms:—Standing with head depressed; dull and oppressed; eye heavy, and eyelids partially closed; resting from one hind foot to the other now and again; ears, legs, and body of a natural heat; the pulse small and weak; the breathing slightly increased (the pulse and breathing very like what we find in influenza); putrid breath; bowels easy and natural; the urine rather high coloured. In a few days its pulse came down to sixty, and continued to do so gradually for ten days until it came down to forty-four, at the same time increasing in strength. I did not see it again for ten days or so, and in the course of
eight days it got decidedly worse, and was now very thirsty and passing urine very often; pulse agitated, and fifty-six; fearfully tucked up in the abdomen; lost condition terribly; anxious for water; bowels now confined; faces light in colour and covered with mucus; eye quite yellow; membrane in the space between the last incisor and first molar of the upper jaw yellowish in tinge; breathing increased; evinced pain on pressure on the false ribs on right side up and down, anteriorly and posteriorly. Next day pulse down to forty-four; anxiety for water and frequent staling gone; and continued thus for about ten days; eating well; was more lively; the breathing more gentle; the bowels kept regular. By the end of this time it fell off again, and shortly after it improved, and was better upon the whole; but the urine was now passed in a small stream, and instead of being amber-coloured was of a reddish-brown appearance; evinced no un easiness when voiding it; continued to eat in a fair way for a week or so. By this time its eye was not so yellow; it left off feeding, and its pulse was now of a very different character—sixty, rather full artery, and rather wiry; it gradually sank, and died quickly. It never coughed during the time it was ill, and it lay on both sides. The eye at first was not yellow, but to me appeared blanched."

Mr. Dixon also sent me the symptoms presented by the foal. He says—"I was called to the foal on the 13th of March (but I saw this foal in December, when it was a nice, thriving, promising animal), but about eight days before I was called to it I was passing the farm and looked in. The foal was in a box. I went in and handled it, and I was perfectly struck by its appearance—just shaggy hair, skin and bone; the hair of a dirty dry colour, in fact quite darkened to a mousy brown, while before it was a lightish brown; pot-bellied. I examined the bay in the rack, took out a handful of dry, musty, black stuff, more fit to litter pigs; so I was called on the day mentioned. It seemed inclined to hang down its head, or often stood with it in the manger, resting on the under jaw; fore legs apart; pulse eighty, with some degree of power in it; eye yellow; the pot-belly gone, and rather tucked up; pain on right side (like the rest). Next day comatose, pushing its head in corner of box, cold legs and ears, and dead next morning. Great debility and weakness were present from the first. I
may add that the foal had never refused eating until the day I was called to it; it ate none after that, and it was not confined in the bowels."

It appears from the history of these cases that cirrhosis of the liver was due to a gradual starvation, and that the atrophy of the hepatic secreting structures was part of the general emaciation—atrophy—of the whole body, which was so rapidly going on, consequent on want of proper food.

Cirrhosis, consisting as it does of an organic change in the gland, tends to a fatal termination, but the rapidity of its course and progress may in some instances be modified by the removal of its cause.

**SOFTENING—RAMOLLISSEMENT—RUPTURE OF THE LIVER.**

Softening and enlargement of the liver is due probably more to repeated attacks of congestion or engorgement than to a truly inflammatory change.

Softening of the liver, very often without there having been any indications during life, terminates in sudden death from rupture of the gland and its capsule. In some instances, however, there are certain symptoms of disease of the organ, such as pallidity or yellowness of the visible mucous membranes, occasional attacks of what appears to be colic, nausea, and irregularity of the bowels.

These attacks of apparent illness usually subside in a short time, leaving the animal seemingly in perfect health. They are, however, apt to recur, the patient finally rapidly sinking from what at first appeared a slight attack of colic, or from some sudden or violent exertion. Death does not always immediately occur from rupture, as it would appear that the liver may become repeatedly ruptured without the occurrence of a fatal haemorrhage. So long as Glisson's capsule remains intact, the haemorrhages are not fatal; and even rupture of the capsule itself, when limited in extent, is not always followed by immediate death. In a case mentioned by Mr. Siddal (Percivall, vol. ii.), a horse had been ill, and subject to frequent fainting fits for upwards of three weeks before it died, which appeared afterwards to have been caused by small ruptures of the peritoneal coverings of the liver in different places, from
all which it rallied, not sinking until the grand rupture had happened. I have met with cases which, remaining dull and off their feed after an attack of colic, have suddenly sunk; and post mortem examination has revealed the existence of several small ruptures, and the final one, of larger size, from which several gallons of blood have escaped into the peritoneal cavity. When small ruptures occur, the hemorrhage becomes arrested by coagulation of the escaping blood; this may become encysted by the formation of a fibrous membrane round it, the extravasated blood becoming shrunk by absorption of its fluid parts, collections of fine crystals of hematin being left.

The symptoms of approaching death are, fainting fits; violent colicky pains; the animal breathing heavily, looking round to its right side; there is rapidly increasing pallor of the mucous membrane; coldness of the mouth, and of the body generally; dilatation of the pupils; the animal propping itself on its limbs, or by the side of the stall; and a running down pulse. If these symptoms be preceded by yellowness of the mucous membrane, by tinged urine, or clay-coloured feces, they are diagnostic that the hemorrhage proceeds from rupture of the liver.

Causes.—The causes which induce softening and disorganization of the liver are identical with those inducing congestion, namely, stimulating food, or want of sufficient exercise; and animals which die from this lesion are generally fat and sleek in the coat.

It is stated that the liver may become ruptured by kicks or blows and severe exertion. This seems to me, however, very improbable, without there being a previous disorganization of the organ.

Post mortem appearances.—On cutting into the abdomen a large quantity of a semi-coagulated dark-coloured blood will be found in the peritoneal sac; the tissues of the body are blanched, and generally intermixed with much fat. With regard to the liver itself, it is found to present two pathological conditions: first, highly congested, enlarged in every direction, its vessels filled with dark semi-fluid blood, and its tissues with much serosity.

Now and then various parts of it present a peculiar mottled appearance, the centre of the lobules being of a dark red colour, whilst their peripheral portion is of a yellowish-white; this condition constituting what is generally termed the "true autogenous liver." Sometimes the organ has acquired the enormous weight of sixty pounds or more.
In the second form, we find that the liver is not so greatly enlarged as in the first, its capsule presents a peculiar slate-coloured tint, and the whole organ may be of the same hue, or stained deeply yellow. Both the gland substance and the capsule are friable, easily reduced to a pulp if touched with the finger, and having more the consistence and appearance of moist, bluish, or yellowish clay than of an organized structure.

Whilst horned cattle, and particularly sheep, are liable to suffer from disorganization of the liver, they seem to escape fatal termination by rupture. Sheep, however, die in great numbers from liver disease about the period of parturition; sometimes without presenting any symptoms of liver disease, or of any disease whatever; sometimes anemic, and occasionally with well-marked symptoms of jaundice.

It is impossible to account for these varieties in the symptoms when the pathological conditions of the organ are identical; and we can only accept them as facts which further researches may throw light upon.

Treatment.—This can be only prophylactic. An inquiry into the causes will show that the errors which lead to the gradual disorganization of this organ are those of improper feeding. In the horse and ox, food highly charged with nutritious elements, and mixed, or but slightly mixed, with that of a coarser nature. In sheep, as already pointed out, food containing saccharine, and but little nitrogenous materials, as when they are fed exclusively upon turnips.

It is therefore necessary, in order to prevent these various alterations of structure, that the proper dieting of animals should always be attended to; that when sheep are put upon turnips, nitrogenous food should be allowed them throughout the whole turnip season in some shape or other, as hay, straw, or small quantities of cake, or bean meal.

JAUNDICE—ICTERUS, OR THE YELLOWS.

Although spoken of as a disease, jaundice is in reality but a symptom of many affections in which the tissues of the body are dyed yellow. Although a result of many organic diseases of the liver, it sometimes occurs when that organ is healthy, and is not rarely absent when it is in a state of disorganization. It
may be produced artificially by ligature of the common duct, which proves that obstruction of the flow of bile into the intestine can cause the disease. It may also occur when there is no such obstruction. And to account for these varieties of causes various theories have been advanced:—First, that the bile is formed in the blood, and is merely removed by the liver, and that jaundice is a consequence of non-separation of the bile; second, that in some diseases the haematin of the blood is changed into bile-pigment, with disintegration of a large number of blood corpuscles, thus assigning a blood origin to the colouring matter of jaundice; third, that it arises from abnormal diffusion of bile, proceeding from some alteration in the circulation of the blood in the liver, or else to defective metamorphosis or impaired consumption of bile in the blood. It is now, however, generally admitted that some of the ingredients of the bile are generated in the liver—namely, the bile acids, glycocholic and taurocholic acids found in the bile combined with soda bases; whilst others—the bile pigment, biliverdine, bilirubin, or cholepyrrhin and cholesterine—exist in the blood, and are merely separated by the liver in a manner similar to the separation of the urea from the blood by the kidneys. It is now admitted that jaundice may arise from two distinct causes:—1st. Suppression or non-elimination; and 2d. From reabsorption of bile.

The two forms are distinguished by the presence of the biliary acids in the urine when it arises from reabsorption, and their absence when due to suppressed secretion. The test is as follows:—To a couple of drachms of the suspected urine add a small fragment of loaf sugar, and afterwards pour slowly into the test tube about a drachm of strong sulphuric acid. This should be done so as not to mix the two liquids. If biliary acids be present there will be observed, at the line of contact of the acids and urine, after standing for a few minutes, a deep purple hue. This result may be taken as a sure indication that the jaundice is due to obstructed bile ducts. On the other hand, the absence of this phenomenon, and the occurrence of merely a brown instead of a purple tint, although in the earlier stages of jaundice equally indicative of suppression, is no indication of the cause of the suppression, which must be gleaned from other circumstances.—(Harley on Jaundice.)

Non-secretion of bile may arise from a variety of causes:—1st.
Innervation; 2d. Disordered hepatic circulation; 3d. Absence of secreting structure, as in atrophy, the invasion of tubercle, and the degenerations.

Jaundice from reabsorption is arranged as follows:—1st. Obstruction by foreign bodies within the bile duct; 2d. Obstruction by inflammatory tumefaction of the duodenum or of the lining membrane of the duct, with exudation into its interior; 3d. Obstruction by stricture or obliteration of the duct; 4th. Obstruction by tumors closing the orifice of the duct or growing in its interior; 5th. Obstruction by pressure on the duct from without; 6th. Obstruction by parasites.

Looking upon jaundice, which is manifested by yellowness of the mucous membranes, as symptomatic of disease, it will be necessary, before the practitioner prescribes any particular treatment, that he should examine the urine in order that he may determine whether it arises from any cause obstructing the flow of bile into the intestinal canal, or from a disordered condition of the liver itself, consequent upon which true bile is not secreted.

Treatment.—In jaundice from suppression, if the cause of the suppression be congestion or inflammation of the liver, the treatment recommended for those conditions is to be pursued. If, on the contrary, those conditions be absent, liver stimulants, as calomel with aloes, may be administered. In the dog, podophyly, with hyoecyamus; or benzoic acid, from 10 to 15 grains, divided into three doses, daily.

As repeated cathartics are not admissible in the lower animals, benefit is often derived from taraxacum, nitro-muriatic acid, and in some cases ox gall. It must, however, be understood that no permanent benefit may be expected if the jaundice be due to cirrhosis or the degenerations. The animal will, however, continue to perform moderate work, provided it be properly and carefully dieted.

In jaundice from reabsorption, the cause of obstruction must be inquired into. If it be due to catarrhal inflammation of the mucous membrane, purgatives, more especially in the horse, are contra-indicated, the constipation of the bowels being more safely removed by mild aperients, such as four-ounce doses of the sulphate of magnesia, or half a pint of linseed oil administered daily until the feces become pultaceous. The
debilitated state of the liver—which sometimes remains after acute attack, and in which the organ performs its functions irregularly, sometimes secreting inordinately, at other times scarcely secreting at all; the inordinate secretion being characterized by bilious purging, some portions of the feces being coffee-coloured, tinged with altered bile; and the non-secreting condition by clay-coloured feces with fecor—is to be overcome by tonics, more especially iron, cinchona bark, or quinine, and a carefully regulated diet. Should the animal indicate, by licking the walls or grinding its teeth, that the stomach and bowels are in an acid condition, great relief will be afforded by the antacids, lime water, or the carbonates of soda or magnesia.

It may be observed that the cause of obstruction will, if long continued, induce such organic changes in the liver itself as to destroy its secretory function; hence we find in such diseases as the "rot" in sheep that the biliary acids are not present in the urine towards the later stages.

In dogs suffering from jaundice and ascites, elaterium, by inducing watery stools, often gives temporary relief, and prolongs the life of the animal.

There are various morbid conditions of the liver, in addition to those already described, found after death, as cancer, tubercle, &c., which need not here be described. The parasitic affections will be described along with "Parasitic Diseases."

**GALL STONES**

Are very rarely found in the lower animals, and there are no symptoms indicative of their presence during life, beyond those which may be induced by any disease of the liver itself. It may, however, be mentioned that in horned cattle which have died from any exhausting disease, with prolonged absence of appetite, the gall bladder is generally distended with an inspissated bile, in which much sediment may be found adhering to the mucous membrane, and that in sheep deposits are found when the gall ducts have been dilated by "flukes."
CHAPTER LXVII

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(Q.) DISEASES OF THE SPLEEN AND PANCREAS.

Diseases of the Spleen.—Various organic changes, as atrophy, hypertrophy, thrombosis, tubercle, cancer, the presence of hydatids, lymphadenoma, and ossification are found post mortem; but there are no symptoms during life which indicate their presence. My friend Mr. Walter Lewis, of Crewe, mentions that in two cases of diseased spleen there was a tendency to run backwards in the stall and elsewhere. I have already stated that I have witnessed this symptom in disease of the duodenum (see ante, page 659). I am informed that in America the horse suffers from an intermittent fever in which the spleen becomes enlarged. It is stated that enlargement of the spleen may be detected per rectum. I doubt, however, its possibility, unless, indeed, the spleen be of an enormous size. In one case which came under my own notice, lymphadenoma of the spleen (shown in the frontispiece of the first edition of this work) was guessed at by the absence of signs of disease of any other organ, slight increase of the white globules in the blood, pallidity of the mucous membrane, a stiffness of the back, and a gradual wasting of flesh. In another case lymphadenoma of the spleen was diagnosed from the history of a case which had a lymphadenomatous tumour in the parotidean region. This animal had latterly fallen off its appetite, and was subject to slight recurring colicking pains, but there were no other symptoms of internal disease. I removed the tumour from the neck, but after finding out its histological character, gave an unfavourable prognosis, being of opinion that another of the same nature was in existence,
most probably in the spleen, giving rise to the colicky symptoms. The animal died a few days afterwards, and a hard lymphomatous tumour twenty-five pounds weight was found in the spleen, involving walls of stomach, duodenum, &c.

I carefully examined the blood of this animal, and found there was scarcely, if any, increase in the white corpuscles (leukæmia), a condition sometimes associated with hyper-development of lymphatic tissue.

I have met with several cases in which the lymphatic glands in various parts of the body, but more particularly in the cervical and subcapular regions, have been enlarged, with development of lymphatic tumours in the spleen and liver.

The same kind of growth is also found associated with farcy, and in the case from which the illustration was obtained the liver weighed thirty-five pounds, being studded throughout with the white tumours shown in the figure.

**Fig. 33.**

The development of lymphadenomatous growths, although found associated with farcy, is not to be considered as due to the presence of the glandereous poison, as they frequently occur when there is not the slightest suspicion of malignant disease.

Lymphadenoma, for a long time confounded with tuberculosis, differs very materially from that product; in fact, whereas tuberculosis rapidly undergoes degeneration, lymphoma has little or no tendency to retrograde. Microscopically lymphoma consists of a delicate network of fibres, within the meshes of which are contained numerous cells—lymph corpuscles. In the early stage of the growth the number of cells is very great, and many of the cells may contain two or even more nuclei, but in a more advanced stage the proportion of cells is smaller, and the reticulum forms most part of the growth.

The physical characters, according to Green, vary according to the rapidity of the growth. The rapidly growing forms, in
which the cellular elements are numerous, are of a greyish colour and soft brain-like consistence, much resembling ecephaloid cancer. These often attain an enormous size, and infiltrate the neighbouring structures. They have been called by Virchow lympho-sarcoma. Those which are more slowly developed, and in which the reticulum constitutes the greater portion of the growth, are much harder in consistence, sometimes being almost cartilaginous.

I have never witnessed the lympho-sarcoma of Virchow. In the case from which the figure was drawn, the tumours, although in the aggregate weighing so heavy, were individually no larger than a thrush’s egg, and were moderately firm in consistence.

The origin of these tumours is a matter of obscurity. I have seen them in the well and in the ill fed animal.

The above remarks will apply to diseases of the pancreas. It must be, however, held in remembrance that the pancreatic juice has the property of converting the fatty matters of the food into an emulsion. The presence, then, of fat or oil in the faeces of the dog, or of any other animal of which fat is an ingredient in its food, points to some diseased condition of the pancreas.
CHAPTER LXVIII.

SPORADIC DISEASES—continued.

(III.) LOCAL DISEASES—continued.

(R.) DISEASES OF THE KIDNEYS.

Owing to the fact that the lower animals are free from mental emotions, the cares and troubles of the world, and that they do not indulge in alcoholic drinks, the kidneys are in a great measure exempt from those diseases which so often destroy human life.

Diseases, however, do occur with which the veterinarian has to cope. Physiologically, the kidneys excrete from the body those materials resulting from metamorphosis of tissue which would, if retained, act injuriously upon the system generally; and the secreted material—the urine—differing as it does in various animals, contains certain constituents, some of them identical, some dissimilar. The presence of these constituents in normal or abnormal quantities, or their absence, indicate to the investigator various morbid conditions of the kidneys, as well as many changes which occur in the body during disease. The urine is naturally alkaline in the herbivora, and acid in flesh-eating animals. It consists of a large amount of water; a nitrogenous substance called urea; an acid—hippuric in that of herbivora, and uric in the carnivora; colouring matter called uro-haematin; inorganic salts; organic substances of an ill-defined nature called extractive matters.

The density of healthy urine of the horse appears to range from 1030 to 1050; that of the ox has a specific gravity ranging from 1032 to 1040; that of pigs 1010 to 1012; and of the goat 1008 or 1009.—(Von Bibra.) The amount of water in the urine varies much, according to the quantities of fluids that have
been taken into the system, and the condition of the intestinal canal, skin, and the surrounding atmosphere.

The amount of urine daily excreted by healthy horses varies, according to the observations of Colin, from 44:033 to 61:646 English pints; and the amount of water in 1000 parts of urine, according to the analyses of Von Bibra, Boussingault, and others, from 880 to 930 parts; whilst in that of the ox, Von Bibra found 912:01 and 923:11; in that of the pig from 980 to 990.

Urea is the most important product of tissue change; it has the same chemical composition as the carbonate of ammonia, to which it is readily converted when heated a little above the temperature of boiling water, or when kept in contact with decaying animal matter. When pure, it crystallizes from a watery solution as a white, semi-transparent, crystalline body with a bitter taste. The crystals are quadratic prisms, with rectangular terminal planes; it readily combines with nitric acid, forming the nitrate of urea, which speedily crystallizes; and the addition of nitric acid to urine is the method of detecting its presence in abnormal quantities. The crystals of the nitrate of urea, when rapidly formed, are flat, shining, rhomboidal plates (see fig. 16, p. 416); when slowly crystallized, fine prisms. Nitrate of urea is soluble in water and alcohol, but only sparingly so when they contain an excess of nitric acid; it is insoluble in ether.

It combines also with oxalic acid, forming the oxalate of urea (Ur. C3O3H4O), which crystallizes in prisms and quadrilateral tubes. Urea forms insoluble compounds with the nitrate or protoxide of mercury.

Although found in the urine, urea is not formed in the kidneys, but is excreted by them from the blood; and, as already pointed out in former chapters, it results not only from metamorphosis of tissue, but also from excess of food, as well as from the decomposition of uric and hippuric acid. Its formation from uric acid has been experimentally proved by Neubauer, who on giving rabbits from 31 to 46½ grains of uric acid with their food, the quantity of urea excreted in the twenty-four hours was augmented from 32:5 to 65:1 grains. Uric acid, when acted upon by permanganate of potash, is transformed into several substances, one of which is urea.
The elimination of urea is also influenced by water. The more water an animal drinks the more urea will it excrete. Common salt also produces an augmentation in the excretion of urea.—(Böcker, Bischoff.) Certain foods diminish the daily excretion of urea, such as sugar, starch, fat; in fact, says Dr. George Harley, “my idea is that all nitrogenized foods augment, and that all non-nitrogenized foods diminish, the amount of urea eliminated by the kidneys.”

Increased elimination of urea occurs in all febrile diseases, and is indicative of abnormal metamorphosis of tissue; and its amount bears a close relationship to the exaltation of temperature and intensity of fever. Retention of urea is a very unfavourable circumstance, and is symptomatic of intense congestion of the kidneys, exudation and haemorrhage into the uriniferous tubes, and desquamation of their epithelium, with destruction of their secreting cells.

Uric acid, C\textsubscript{10}H\textsubscript{4}N\textsubscript{4}O\textsubscript{8}, is a white crystalline, feebly acid, tasteless, organic substance, insoluble in ether or alcohol, and but sparingly so in water: 2000 parts of hot and 11,000 parts of cold water are required to dissolve one part of uric acid. It is soluble in strong sulphuric acid, and is transformed by dry distillation into urea, cyanic acid, hydrocyanic acid, carbonate of ammonia, and an oily coal. It unites with bases such as potash, soda, or ammonia, forming with them crystalline urates. The urine of herbivorous animals contains little, if any, uric acid; but it is found in the solid urines of serpents, birds, and insects, and in the liquid urines of omnivora and carnivora, in combination with potash, soda, and ammonia.

The pathology of uric acid is of little consequence to the veterinarian. It is derived from the same source as urea, and whatever accelerates oxidation increases the amount of urea and diminishes the uric acid, and whatever diminishes oxidation decreases the urea and increases the uric acid in the urine, thus proving that urea is a more completely oxidized product than the uric acid. In the dog and other carnivora uric acid calculi have sometimes been found.

Hippuric acid (C\textsubscript{10}H\textsubscript{8}N\textsubscript{4}O\textsubscript{8}) is a beautiful white crystalline, slightly acid body, constantly found in the urine of all but the purely carnivorous animal. It is soluble in 400 parts of cold water, and its solution is sufficiently acid to redden litmus.
paper; it is also soluble in ether and alcohol. Its quantity in
the urine varies greatly. When the quantity of urea is small
that of hippuric acid is almost always large, and vice versa.
According to Von Bibra and Boussingault it varies from 5 to 15
parts in 1000 of the urine of healthy horses; and it has been
stated by some chemists that the urine of horses which are sub-
jected to very hard work contains no hippuric acid, but much
benzoic acid instead. "The last part of the statement," says
Mr. Gagee, "seems doubtful, though it would appear that hard
work checks the excretion of hippuric acid, and increases the
quantity of urea excreted." The observations of Maack oppose
this conclusion. He found that horses kept standing in the
stable passed very little hippuric acid, but large quantities of
urea, and Dr. G. Harley made similar observations regarding
London stall-fed cows. They did not, however, examine the
urine after these animals had been exercised; their experiments
are therefore incomplete. Hippuric acid is increased in rheu-
matism, red water, and in diseases of the respiratory organs; in
fact, in all conditions in which the blood is imperfectly aërated,
either from obstruction to free respiration or sudden arrestment
of the cutaneous functions, as well as from an imperfect condi-
tion of the blood itself, rendering it incapable of oxidation.

Extractive matters, as creatine, creatinine, lactic acid, and
benzoic acid, which is transformed into hippuric acid in the
body—for it has been found that when benzoic acid is given to
an animal an almost equal amount of hippuric acid is elimi-
nated by the kidneys—are found in the urine. Sometimes urine
contains a large quantity of mucous derived from the pelvis of
the kidneys, ureters, bladder, or urethra, indicating some degree
of irritation of the mucous membranes. After parturition, as
might be expected, the urine generally contains much mucus,
derived from the mucous membrane of the vagina.

Saline matters, consisting of various materials from the food
and tissue, as the chlorides, phosphates, sulphates, and carbonates,
are present in healthy urine, whilst other salts, originating in
mal-nutrition of tissues, or from defective secretion of other
organs, such as the oxalates, are sometimes met with. For the
method of determining the presence of these, the reader is referred
to Harley on the Urine, Roberts on Urinary and Renal Diseases,
Beale, and others. The most common inorganic deposit which
is found in the urine of the horse is the carbonate of lime, which appears as a chalky sediment if the urine be kept in a vessel for some hours.

In the ox and sheep, when fed upon turnips and linseed cake, the urine generally becomes highly charged with the phosphates, which are very often spontaneously precipitated upon the mucous membrane of the bladder, urethra, and the long hairs surrounding the prepuce. I have some specimens in my possession of the ammonio-magnesian phosphate in the form of tubes deposited upon the hairs surrounding the preputial opening. The occurrence of phosphatic deposits in the lower animals results from the food upon which they are kept being highly charged with phosphatic salts. We consequently find that when animals are fed upon turnips and other foods grown upon land highly manured with dissolved bones and other phosphatic preparations, that the urine becomes highly charged with these materials, and that they are apt to be deposited in the form of gravel upon the mucous membrane of the urinary passages, more especially upon the occurrence of any cause of irritation, such as a common cold or other catarrhal affections. They sometimes induce obstruction to the flow of urine if situated in the urethra, or a suppression of its secretion, either by extension of the irritation primarily excited in the urethra or bladder to the kidneys, or when deposited in the pelvis of the kidneys by an inflammation of the glands. In order to overcome the further deposition of this salt a change of diet is essential, and to dissolve what is actually deposited, nitric acid in fifteen-drop doses, largely diluted, may be administered three times a day.

Pus or blood are occasionally met with in the urine, and indicate irritation or inflammation of the urethra, bladder, or kidneys. When from the urethra, bladder, or ureters, the extravasated blood has no definite form, but if from the kidneys, blood and lymph are moulded into the shape of the uriniferous tubes.

Albumen is recognised by its property of coagulating upon the application of heat and of nitric acid. If the urine be alkaline the albumen may not coagulate upon boiling, but if a few drops of nitric acid be added it is immediately precipitated. Sometimes, if the urine be boiled, a precipitate may be formed, consisting of the phosphates; these are dissolved by nitric acid.
Again, if the urine contain much urea, a precipitate is formed when nitric acid is added; this is, however, dissolved if the liquid be boiled, and the determining test for albumen is that it is neither dissolved by heat nor nitric acid. The presence of albumen in the urine is diagnostic of congestion, inflammation or degeneration of the kidneys, or that condition of the system already described under "Red Water." Albumen is also present in the urine in some cases of indigestion, and indicates that the albumen of the serum is in a condition which renders it unfit for the nutrition of tissues.

The occurrence of oxalic acid in the urine has already been referred to.—(See Oxaluria)
CHAPTER LXIX.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(A) DISEASES OF THE KIDNEYS—continued.

INFLAMMATION OF THE KIDNEYS—NEPHRITIS.

A rare disease in the lower animals, but in human medicine it is described under three heads, namely—Suppurative, Interstitial, and Tubal. Except from the irritation of a calculus, suppurative nephritis—pyelitis—is a very rare form of disease in the lower animals. I have, however, met with a few cases where it has arisen independently of such source of irritation. In one case (a cow) it was associated with inflammation of the urino-genital mucous membranes, consequent upon difficult parturition; indeed it seemed to be due more to the absorption of infective materials from the inflamed mucous membranes, which discharged a fetid, purulent material very profusely, than to an extension of the inflammation. The next case was that of a foal two days old, which had died from acute suppurative arthritis. A post mortem examination revealed not only the presence of pus in the tissues surrounding the articulations, but sundry purulent points in the kidneys, the pus in which being more or less inspissated or caseous.

I look upon this case as important, as to some extent it supports the view that "joint disease" occurring in young animals is not always a primary disease, but secondary to the formation of pus in other parts of the organism. Generally, however, nephritis embraces all the structures of the kidneys, often commencing in the mucous membrane of the unisierous tubes, afterwards involving the parenchyma, and terminating in resolu-
DISEASES OF THE KIDNEYS.

Dehydration, or in desquamation of the lining of the epithelium and degeneration of the secreting structures, sometimes in suppuration, and in very rare instances gangrene.

Causes.—Nephritis is said to occur from injuries, such as blows and strains. My experience leads me to think that this idea is exaggerated, and that it occurs, and that but rarely, from the internal administration of irritant diuretics, as turpentine, the resins, or cantharides, the absorption of cantharidine from large blisters, the irritating effects of croton oil when given as a purgative, and still more rarely from the effects of stimulating food, or of the long-continued effect of cold, such as cold water dropping upon the animal's back, directly applied to the loins. Many ailments and injuries are mistaken, I think, for nephritis, more especially if they are characterised by a straddling or stiff gait.

Symptoms.—There is considerable fever and colicky pains; indeed the malady closely simulates colic with fever. There is a hard, frequent pulse; increased thirst; short, rapid breathing; hot, clammy mouth, and constipation of the bowels. There may be some stiffness of the loins and disinclination to move, but it by no means follows that stiffness, a straddling gait, tenderness of the loins, arched back, are constant symptoms; indeed, I am led to conclude that they are present only in the minority of cases, and that the only signs by which the true nature of the disease can be determined are a scanty secretion or total suppression of urine, desire to micturate frequently, the animal stretching itself in vain attempts, passing perhaps but a few drops of a concentrated, highly coloured, and irritating secretion, which, if carefully examined microscopically, will be found mixed with sanguineous or fibrinous casts of the uriniferous tubes, blood globules, epithelium, and even pus cells. If tested by heat or nitric acid, a more or less abundant precipitate of albumen will be thrown down. In those instances where there is total suppression of urine, the application of the determining test is impossible. The true nature of the disease may, however, be arrived at, from the fact that when fever, with colicky pains, is present, in addition to emptiness of the urinary bladder, frequent attempts to urinate, but no urine being discharged, that the non-secretion is due to inflammation of the kidneys, which are unable to perform their functions in consequence of the inflam-
matory process. Cases now and then occur in which the only symptoms present are suppression of urine, with fever; but in other instances there are signs of pain manifested by frequent lying down, rolling, sighing, &c.; whilst in others the seat of pain is pointed at by the animal turning round and endeavouring to bite or scratch its loins. In one instance the symptom was very marked, and called forth the observation from the attendant that the horse wanted to bite its near hind leg, which was elevated and brought forward as if for that purpose; the animal, however, seemed to desire to bite its back, but was unable to do so. Should the suppression—ischuria—be prolonged, other symptoms, namely, those of blood poisoning—uramia—arise. The retention of urea in the blood does not affect all animals alike. In the dog, insensibility and coma soon occur; but in the horse the effect seems to resemble a moderate alcoholic intoxication; the eye becomes brilliant, there is partial unconsciousness, but no loss of motor power. In one case, where total suppression continued for five days, no signs of coma or even somnolence were observed; but the animal became incapable of directing its movements, which were automatic, and from right to left, in which direction it continually moved round the box, and no force could compel it to move in the contrary direction. As the system becomes loaded with urea, the faeces and secretion of the skin emit a strong uriniferous or even ammoniacal odour; the breath becomes fetid; the bowels constipated and tympanitic, with frequent vomition in the dog. In the case above mentioned, it was observed that the near (left) side was covered by a continual sweat, which became more and more uriniferous as the disease advanced; the skin of the opposite side was dry, hard, the cost stering, and on the fourth day the near hind limb was partially paralyzed; and the horse was frightened if it were suddenly touched or approached. In the stallion, retraction of the testicle on the affected side may be present.

Post mortem appearances.—In the acute form of general nephritis one or both kidneys may be involved; generally one is more especially affected, being enlarged, of a dark colour, and streaked with patches of congestion. It is easily lacerable, and if cut with the knife, a deep-coloured fluid flows from the cut surface, which, if examined microscopically, will be found to
DISEASES OF THE KIDNEYS.

contain pus cells in abundance; there is exudation into the tubes and desquamation of the epithelium, constituting "epithelial casts." Pyelitis, however, gives rise to the formation of abscesses, which are principally confined to the cortex of the kidney. These vary in size from a pin-head to a pigeon's egg, or even larger. Abscesses are multiple and surrounded by congested tissue, and sometimes by submucous haemorrhage; this was specially observable in the cow referred to. They are easily seen through the capsule of the kidney as many yellowish white spots.

Interstitial nephritis consists of an inflammation of the interlobular connective tissue, similar to cirrhosis of the liver, and leads to contraction of the affected kidney.

Treatment.—This must be according to the ordinary principles of the treatment of inflammation. If the pulse be strong, a full bleeding will be of much service, not only allaying the febrile disturbance, but, by acting as an evacuant, removing much effete material from the economy. The intestinal canal is to be freely acted upon by cathartics, for direct experiment has shown that the urea, &c. which accumulate in the blood are by this means eliminated from the body, and the symptoms of uresmic poisoning delayed. For the horse, aloes; the ox, the sulphates of magnesia or soda; the dog, calomel and jalap, with enemas of warm water, warm fomentations or poultices to the loins, succeeded by mild mustard applications.

If the suppression continue for several days, or if at any time uresmic intoxication is apparent, it becomes necessary to excite the secretion of urine, and the best and safest method of doing this is by the application of digitalis to the skin in the form of a decoction, repeatedly applied as a fomentation to the loins, or as a poultice. It must, however, be discontinued immediately after the kidneys have commenced to react. I can speak with great confidence of this remedy if thus applied.

If pain be a prominent symptom it must be relieved by opium.

It is scarcely necessary for me to say anything against the application of causticidine blisters, as the practitioner is aware that they have a most irritating effect upon the urinary organs.

As sequelae to nephritis, atrophy and degeneration of the gland may result. If the inflammation be confined to one, it is
found that the other kidney generally becomes hypertrophied, having a double function to perform. In the case mentioned, where the suppression continued for five days, the left kidney was found to be, when examined some years afterwards, a mere flabby bag, its substance destroyed, and the ureter impervious; the right kidney, on the other hand, was much enlarged, and almost healthy. This condition of atrophy of one, and hypertrophy of the other, was diagnosed at the time it was attended, for the enlarged organ was easily detectable by the hand introduced into the rectum. Both Percivall and Gamgee quote a case of suppuration of the kidney, described by D'Arboval, occurring in a mare which had fallen into a hole.

**ALBUMINURIA.**

The occurrence of albumen may be due to various causes unconnected with disease of the kidneys, as in "red water" in cattle, some forms of indigestion in the horse, as well as from cerebro-spinal irritation. The application of large cantharidin blisters may also be followed by albuminous urine. According to some this is due to the toxic effects of cantharidin upon the blood, inducing a condition of that fluid simulating that resulting from the action of morbid poisons. According to others it is a result of the direct irritating effects upon the kidneys of the absorbed cantharidin. This latter view seems to me to be the more correct one, for not only does it irritate the kidneys, but the urinary passages generally, as manifested by frequent and difficult urination—*strangury*—which is best treated by opium, demulcents, as linseed tea, and bicarbonate of soda.

Persistent albuminuria arises from that degenerated condition of the kidney termed by medical writers "Bright's disease." It is, however, very rare in the lower animals. It is described by veterinary authors under the term of albuminous nephritis and granular degeneration of the kidneys.

The urine in this disease is permanently albuminous, and if examined microscopically will be found to contain a number of thread-like cylinders, which are in fact slender fibrinous coagula moulded to the shape, and discharged from the urinary tubes of the kidneys. They are generally studded with minute epithelial cells, which have been detached from the surface of the urini-
ferous tubes, and in some instances they are mixed with oil globules, which denote not only the presence of desquamative nephritis, but of fatty degeneration also.

The anatomical characters of the kidneys in this disease are of two kinds, and are spoken of as the large white and the small red kidney. If a longitudinal section of the large kidney be made, its cortical portion is seen to be much increased; the organ is soft in consistence, smooth upon its surface and upon its investing membrane; whilst the small kidney is hard and red, rough upon its surface, and its investing membrane firmly adherent.

Symptoms.—In addition to some stiffness of gait, there is continued desire on the part of the animal to stretch out in the stall, and in this position to continue, as described by Mr. Percivall, "with its fore legs extended under the manger, and its hind ones backwards, unless disturbed, all day long, not for the purpose of staling, but apparently because that posture seemed an easy or a comfortable one to it." The diagnostic signs are present in the urine itself, which is albuminous, containing fibrous casts of the uriniferous tubes, epithelial cells, or perhaps oil globules, whilst in quantity it may be very materially diminished or increased. I had the opportunity of watching the progress of a case for a number of years, and of making a post mortem examination after the animal's death. The general health seemed but little affected. There was some shortness of breath, the animal never lying down, and some stiffness of gait; the urine varied in colour and density, sometimes dark, sometimes pale, but always albuminous and copious in quantity. The horse became paralyzed, and was destroyed. Examination of the kidneys showed that they were red and small, with numerous cysts, containing a thin transparent fluid in their interior. I was unable to account for the copious secretion of urine, but I find the same thing occurs in man; and that in the large white kidney the secretion is scanty, has a higher specific gravity, and contains clear, fibrous, wax-like, and sometimes oily casts, with occasionally a little blood, and is frothy; whilst in the small red kidney the urine is copious as to quantity, and in the advanced stages pale, of a very low specific gravity, and contains granular casts of the uriniferous tubes.

Treatment.—When resulting from degenerative changes in the
glands, treatment of albuminous urine can only be palliative, relieving the kidneys as much as possible from the labour of elimination, by keeping the bowels in a relaxed condition by proper food, the skin warm, avoiding exposure to cold, and preventing anaemia by mineral tonics or the mineral acids, and putting the animal to such labour as it is capable of performing. When arising from other than disease of the kidney, albuminous urine, which is but a symptom, will disappear as the causes of such diseases are removed.

FLOATING KIDNEY.

I have met with one case where the right kidney in a cat was situated subcutaneously between the two last ribs. Supposed to be a tumour which had arisen in consequence of a bite from a dog, it was removed by me early in 1879; and, what is most interesting, the cat was none the worse of the operation, and is alive at the present time and as well as ever.

HÆMATUREIA—RENAL CALCULI.

The occurrence of blood in the urine is due to a variety of circumstances, as acute congestion, degenerations already described, cancers, melanosis, and to the presence of calculi. Renal calculi in the horse are composed of the carbonate of lime, and their presence is discoverable by the condition of the urine, which is charged with earthy materials, and by intermittent discharges of blood, occasional colicky pains, more especially after the animal has been severely worked or exercised. They are, however, exceedingly rare, and are best treated by the administration of hydrochloric acid, by the avoidance of food and water rich in saline matters, and by keeping the digestive and secretory functions well regulated by diet, careful grooming and exercise when admissible, and the avoidance of hard, calcareous water. In some instances the calculi become impacted in the ureters, inducing a more or less rapid degeneration of the kidney and suppuration within its substance, causing extreme agony and death. If the ureter becomes much dilated, the dilatation may be discovered by an examination per rectum, in the form of a fluctuating swelling upon either side of the pelvis.

SPORADIC DISEASES—continued.

(III)—LOCAL DISEASES—continued.

(S.) CYSTITIS, OR INFLAMMATION OF THE BLADDER.

Excerpt as a result of the irritating effects of cantharidine or croton oil absorbed from a blister, or administered internally, I have never seen this affection in any of the lower animals, and am disposed to coincide with many veterinarians, that it never occurs except from the above causes.

Symptoms.—These are manifested primarily by excitement, followed by prostration of strength, the animal appearing to suffer much pain and distress; the urine is passed frequently, and with difficulty and pain; the faces are covered with mucus and mixed with blood. When induced by cantharides or croton administered by the mouth, the inflammation extends throughout the whole alimentary canal, and there is redness of the buccal mucous membrane, with difficulty of swallowing, and attempts at vomiting in horses and cattle, the genito-urinary organs being also much affected; but if the above irritants be absorbed from a blistered surface, their effect is concentrated upon the urino-genital organs, causing in most animals strangury and apparent sexual excitement, and if these symptoms are not soon allayed, death will result in two or three days.

Treatment.—If from a blister, wash and cleanse the blistered part; internally, hyoscyamus or opium, bicarbonate of soda, demulcents, such as linseed tea, mucilaginous drinks, milk, and white of eggs will be found beneficial.

RETENTION OF URINE.

An inability, total or partial, of expelling by natural effort the urine contained in the bladder. It is caused by spasm of the
neck of the bladder; so induced, it is often a complication of colic; paralysis of the bladder. Retention is a common complication in parturient apoplexy and in paraplegia; enlargement of the prostate in aged males; cystic or urethral calculi; cancer of the penis; any cause of obstruction at the urethral opening; prolapso of the uterus or vagina, and excessive accumulations of feces in the rectum, and of dirt in the sheath. Inability to urinate may also result independently of the above causes and of any disease of the bladder or urethra, when an animal is unable or unwilling to rise upon its feet, as in azoturia, laminitis, or paralysis.

The symptoms are frequent and ineffectual attempts to urinate; if standing, the animal will stretch itself out, strain violently, and groan with pain, discharging but a few drops of urine, or none at all. Examination per rectum will enable the practitioner to feel the distended bladder with the hand, and this distension of the bladder is the diagnostic symptom. Such an examination will also often enable him to discover the cause; if from enlarged prostates, these will be felt as oval bodies immediately within the pelvis pressing upon the urethra. I have one case recorded where the animal had suffered, according to my informant, for five weeks from what appeared to be incontinence of urine—there being a continual dropping of urine night and day—but which proved, upon examination, to be a case of retention from the pressure of large prostates. The bladder was enormously distended, and the continual dropping of urine was the mere overflow; upon the catheter being introduced relief was immediately given by the withdrawal of a large quantity of urine. It was necessary to introduce the catheter two or three times a day for about a week, when the enlarged prostates, under the influence of iodine internally administered, and applied as an ointment to the perineum, diminished in size, and permanent relief was afforded.

Paralysis of the bladder, if not caused by cerebro-spinal or spinal derangement, may be induced by retention of urine, as when an animal is compelled to perform a long journey without the opportunity of relieving itself. In this case the muscular fibres of the bladder, unnaturally stretched by the pressure of the contained urine, lose their tonicity, and become unable to contract upon their contents. Whatever be the cause of
the retention, relief must be afforded by the introduction of the catheter, and it is highly important, in all cases where animals retain the recumbent posture, to examine the condition of the bladder, and afford the necessary relief by the introduction of the catheter. Sometimes, however, the evacuation may be effected by firm but not violent pressure upon the bladder with the open hand introduced into the rectum, taking care that the mucous membrane of the rectum be not injured by the finger nails or by too violent pressure. In introducing the catheter in the cow, care must be taken not to injure the thin, delicate, membranous valve which guards the urethral opening; and in order to introduce the catheter without causing injury, the valve is to be lifted upwards by the finger, and the point of the catheter carefully introduced beneath it. If retention be due to the accumulation of dirt within the sheath of the penis, it may not be necessary to introduce the catheter, but to wash the parts thoroughly with soap and warm water; a little carbolic acid in the latter will render this operation much less offensive to the nostrils by destroying the fetid smell.

INCONTINENCE OF URINE.

This is the reverse of retention, being a continual flow of urine. It arises from a variety of causes, namely, paralysis of the sphincter vesicae, the muscular power of the walls of the bladder remaining intact; calculi; and from pervious urachus shortly after birth.

For the treatment of the two latter causes see Principles and Practice of Veterinary Surgery; and for that arising from paralysis cathartics may be necessary, succeeded by nux vomica and cantharides, with injections of cold water into the rectum.

"Incontinence is said to occur in pigs after eating of polygonum, hydropiper, and lapathifolium."—(Gamgee.)

The following terms are applied to the checked discharges of urine:—suppression—ischuria; painful discharge of little urine—dysuria; and the passage of urine in drops—strangury.
CHAPTER LXXI
SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(T.) HYSTERIA.

Concurrent with the period of oestrus in the female, the following symptoms—clenching of the jaws, grinding the teeth, difficulty of swallowing, some degree of trismus, squinting of the eyes, tonic spasms, alternating with those of a clonic kind, continual kicking in an irregular uncontrolled manner with one or both hind feet, stamping of the fore feet, and other signs of nervous excitement, have been observed in the mare and female ass.

In one case that I saw, the two fore shoes and one hind shoe had been thrown off by the violent kicking and stamping. Attempts were made to remove the remaining one, which was loose; they were, however, unavailable, as the slightest touch caused a most violent kicking. The animal would fall, the whole trunk and neck being perfectly rigid, whilst the limbs continually moved in a violent and spasmodic manner. The power of volition seemed to be completely lost. The gluteal muscles were exceedingly hard and prominent. The rapid opening and closing of the vulva and its highly injected mucous membrane indicated the hyperesthesia of the genital organs. Urine was passed abundantly, at first pale and watery, but afterwards highly coloured, and loaded with solid matters.

In another case the symptoms were rather different. The animal was prostrate, rigid, with its eyes turned upwards, as if in a trance. They were both bled, and an endeavour was made to nauseate them with aloes, and to allay the nervous irritability with opium. One recovered, the other died. For the prevention of this condition I can only suggest that the sexual desire be gratified if possible, whenever such a state of excitement short of the above presents itself.
CHAPTER LXXII.

SPORADIC DISEASES—continued.

(III) LOCAL DISEASES—continued.

(U.) DISEASES CONCURRENT WITH OR IMMEDIATELY SUCCEEDING PARTURITION.

Accidental conditions connected with parturition, requiring the aid of a surgeon, will be found fully described in the Principles and Practice of Veterinary Surgery, as it is my intention to confine my present observations to those of a more purely medical character.

Under the common term "milk fever," at least three separate diseases are generally described, namely, parturient fever, parturient apoplexy (already described), and acute metritis.

PARTURIENT FEVER.

Definition.—A benign form of fever, seen in the cow, mare, &c., occurring about the second or third day after parturition, and generally terminating in recovery in from twenty-four to forty-eight hours.

The symptoms are those characteristic of general febrile disturbance; the pulse generally full and strong, the breathing accelerated, the visible mucous membranes injected, the secretion of milk suspended, the mammary gland hard and slightly erythematous, bowels constipated. The cow may assume the recumbent posture, but the power of maintaining the standing one is not lost, nor are there any signs of unconsciousness or of cerebral disturbance. Unlike parturient apoplexy, it attacks animals of all ages, but it is most commonly met with after the first parturition, and is induced by cold, or some dietetic error,
and seems to be connected with that condition of excitement associated with the secretion of milk.

_Treatment._—The treatment of this affection is very simple, a mild oleaginous purgative, combined with a dose of the spirits of nitrous ether, warm clothing, and a restricted diet being all that is required.

**ACUTE METRITIS, OR INFLAMMATION OF THE WOMB.**

A very fatal form of inflammation, occurring in a few hours or within two or three days after parturition.

Whilst parturient apoplexy and parturient paralysis are generally met with in the cow, acute metritis, or, more correctly, metro-peritonitis, attacks the cow, mare, ewe, the bitch, and the sow.

**Pathology._—A diffuse inflammation, primarily situated in the mucous membrane of the uterus, soon, however, extending to the uterine veins, giving rise to the formation of clots or thrombi, and extending to the peritoneum and intestines. The inflammation is characterised by its tendency to spread rapidly over a large surface, and by the rapid formation of an abundant quantity of a dark chocolate-coloured fluid exudation, which stains the tissues of the organs involved, and is poured out upon the free surface of the uterine mucous membrane, from whence it is discharged _per vaginam_, and which, by its acridity, causes much irritation and straining—tenesmus. Examined microscopically, it is found to consist of the _débris_ of disintegrated blood globules, pus, and blood corpuscles, and an abundant quantity of granular material slightly intermixed with shreds of imperfect lymph floating in a reddish-coloured serosity.

This affection may be looked upon as being due to pyemic or ischemic poisoning, the whole mass of blood becoming altered in its character, dark, feebly coagulable, with the appearance of secondary spots of inflammation and ecchymosis in the lungs, the brain, and other organs.

The occurrence of the disease is due to over-fatigue, as from over-driving immediately prior to the act of parturition, wounds inflicted upon the uterus or vagina during difficult delivery, the retention of the foetal membranes, which, rapidly decomposing, infect the blood by absorption of the putrescent products.
may also be induced by obesity, more particularly in the bitch, exposure to cold, or any other debilitating influence.

The disease may occur within a few hours after parturition, or its appearance may be protracted to the third or fourth day, and the chances of a favourable termination are in accordance with the lateness of the attack. If occurring within the shorter period, it is almost invariably fatal.

Symptoms.—Restlessness, paddling of the hind feet, loss of appetite, almost a total suppression of milk, the few drops that might be squeezed from the mammary gland being of a bluish tint, thin, and watery, sometimes of a reddish or even chocolate colour, containing granular matter, more or less curdled in appearance, and exhaling a peculiar odour. The vulva is small, contracted; the vaginal mucous membrane sometimes of a dark purple hue, or a deep red colour, with petechial spots and purple streaks. There is violent straining, discharge of a coffee-coloured, fetid liquid, and, as the disease advances, an exhaustive fetid diarrhoea. The prostration of strength is extreme; the pulse is feeble, thready, and very rapid; the heart’s action tumultuous; the belly tympanitic; the surface of the body cold. So long as sufficient strength remains, the animal will frequently lie down and rise again; will kick the belly, and show other signs of abdominal pain; and in the mare these symptoms are sometimes complicated with those of inflammation of the feet. As the debility increases, the animal will be unable to maintain the standing posture, but whilst recumbent, will still manifest symptoms of abdominal pain by rolling from side to side, looking round at the flank, and by violent attempts to regain its feet; the pulse becomes feebler and feebler; the breathing hurried and thoracic; at last the eye becomes amaurotic, and complete unconsciousness sets in; the animal dying in from twelve hours to perhaps two days after attack.

Whilst practising in Mold, I had the opportunity of seeing this disease extensively. Mold at that time was the terminal station of the railway, and calving cows were driven in from long distances in Wales for the purpose of being conveyed to the English markets. They would sometimes calve on the road, and were of necessity driven onwards with the rest of the herd, and too often succumbed to this fatal malady.

Treatment.—Bleeding, purgatives, and depressants of all kinds
hasten the fatal termination, and the only hope of recovery must be based upon attempts to restore the diminished vital powers by the administration of alcoholic stimulants, the removal of the uterine and abdominal pain by opium and hot fomentations to the loins and abdominal walls, and to destroy the septic properties of the contents of the uterus, and soothe its irritated and inflamed mucous membrane by injections of warm water containing opium and antiseptics, such as "Condy's Fluid," hyposulphite of soda, or carbolic acid largely diluted.

Amongst ewes, the disease is known by the term "inflammation," and great success has been obtained in its treatment by the application to the inflamed uterus of carbolic acid one part, olive oil ten parts. The same treatment is applicable to other animals.
CHAPTER LXXIII.
PARASITIC DISEASES.
REMARKS ON CLASSIFICATION—NEMATODA—TREMATODA—CESTODA—ACANTHOCEPHALA—DIPTERA—TRACHEARIA—TABLES OF ENTOZOA.

CLASSIFICATION OF PARASITES.
Parasites are distinguished as Endoparasites when living in the interior of their hosts, and as Ectoparasites when external. With the Ectoparasites we have at present nothing to do, but will confine our attention entirely to the Endoparasites. Among the most important endoparasitic animals or Entozoa are those spoken of collectively as “worms,” including not only roundworms resembling the earth-worms (Lumbricus terrestris), and hence popularly spoken of as Lumbricoids, but also worms resembling a band or a tape (tape-worms), or a leaf (flukes), as well as the thorny-headed worms (Echinorhynchus). The round-worms and thorn-headed worms form together the class Nemathelminthes, while the flukes and the tape-worms constitute the class Platyhelminthes. These two classes form the parasitic division of Cuvier’s sub-kingdom Vermes.

These classes are further broken up into natural orders; thus the class Nemathelminthes includes the two orders Nematoda and Acanthocephala, and the class Platyhelminthes the two orders Trematoda or flukes, and Cestoda or tape-worms.

These natural orders are further subdivided into families, genera, and species. Then, again, it must not be forgotten that there are other kinds of internal parasites, commonly designated “bota.” These creatures are not usually classed with the entozoa, or helminths proper, because they are merely the larval stages
of growth of various species of gadfly. These flies are generally included in the genus *Estrus* of entomologists, the *Estridae* forming a rather numerous family of the class *Insecta*, and belonging to the order called *Diptera*. As the attention of the profession is often called to these singular creatures, it will be desirable to give a brief account of their development and habits.

There is yet another series of internal parasites, long ago called Pentastomias, from the notion that they were furnished with five mouths. These worms are also occasionally brought under the notice of the practitioner of veterinary medicine; and in one remarkable instance recorded by the late Professor Dick, three of these entozoa caused the death of a valuable sporting dog. These Pentastomias, in fact, are allied to the true ticks, and therefore must be grouped along with all those spider-like creatures, which, in common with the spiders themselves, breathe by means of peculiar air-vessels termed trachee. In other words, the Pentastomias belong to the order *Trachearia*, forming a division of the class *Arachnida*.

It thus appears that, without taking into consideration certain minute parasitic organisms belonging to the lowermost class of animals, and misnamed "cattle plague bodies," we have to deal with no less than six well-marked orders of invertebrate animals, one or more species of each of these orders being liable to play the part of parasite within the body of some one or other of our various domesticated animals.

To such of the parasites as have an especial interest for the profession, and which are included in one or other of the six orders, namely, *Nematoda*, *Trematoda*, *Cestoda*, *Acanthocephala*, *Diptera*, and *Trachearia*, the reader's attention is now invited.

**Classification of Entozoa.**

**Sub-Kingdom Vermes (Worms).**

Cl. I. *Platyhelminthes* (Flat-worms).

(N. O. 1.) *Cestoda*.

(Fam. a.) *Trematidae* (Tape-worms).

Gen. *Teneia*.

(Fam. b.) *Bothrioccephalidae* (Pit-headed worms).

Gen. *Bothrioccephalus*. 
(N. O. 2.) *Nematoda* (Flukes).
  Gen. *Dictyocaulus.*
  *Amphistomata.*

Cl. II. *Nematelminthes* (Round-worms).
  (N. O. 1.) *Nematoda* (Round-worms proper).
    (Group a.) *Polymyaria.*
      Gen. *Ascaris.*
      *Eustrongylus.*
      Filaria (including *Spiroptera*).
    (Group b.) *Meromyaria.*
      Gen. *Oxyuris.*
      *Strongylus* (including *Dochmius*).
    (Group c.) *Holomyaria.*
      Gen. *Trichina.*
      *Trichocephalus.*

(N. O. 2.) *Acanthocephala* (Thorn-headed worms).
  Gen. *Echinorhynchus.*

**SUB-KINGDOM ARTHROPODA.**

Cl. I. *Insecta.*
  N. O. *Diptera.*
    Fam. *Oestridae.*
    Gen. *Oestrus*; the larvae of some species are
    *Entozoa.*

Cl. II. *Arachnida.*
  N. O. *Trachearia.*
  Gen. *Pentastoma.*

**NEMATODA.**

This order is treated of first because it includes the parasites emphatically called "worms." When a horse is said to have worms, we know that in nine cases out of ten the animal is passing lumbricoids of large size (*Ascaris megaloccephala*), or it is troubled with maw-worms (*Oxyuris curvula*). In like manner, when a dog is said to have worms, it is either meant that the animal is passing or throwing up round-worms (*Ascaris marginata*), or that it is parting with the falsely so-called maw-worms, which, after all, are neither more nor less than the free and independent segments or proglottides of some species of tape-worm. Worms
In cattle and sheep are not often spoken of as such, and little attention is paid to those of the pig. With the cat, however, it is far otherwise, for we have known veterinarians whose assistance has been eagerly sought in view of ridding this domestic pet of its internal enemies, and especially of the nematode entozoan called *Ascaris mystax*. In addition to the above, there are other species belonging to the nematode order, to which a larger interest is, or ought to be, attached by the professional man. To this series belong the little flesh-worm (*Trichina spiralis*); the thread-worm which occasions the "lamb disease" (*Strongylus filaria*); the very similar nematode that produces husk or hoove in cattle (*Strongylus murruris*); and the worm which gives rise to aneurysmas in the horse and ass (*Strongylus armatus*). No member of the veterinary profession should be totally unacquainted with the natural history of these important species of parasite.

Except as regards the *Trichina spiralis*, it cannot be affirmed that we have an entire knowledge of the course of development undergone by any of the above-mentioned nematodes. It is true that, with more or less deviation from a common plan, all of them must pass through similar stages of growth, from the time of their first formation in the egg up to the period of sexual maturity. All, moreover, must in some way or other conform to a known law of their existence, which involves at least one change of residence before they can acquire the adult condition within the body of the last or ultimate bearer. Herein lies the difficulty in tracing out the development of most of the species: nevertheless, from the facts already made known by experimental research, it is not too much to hope that we shall hereafter become possessed of a knowledge of all the more important phenomena connected with the development of the nematode worms.

The *Trichina spiralis*, as ordinarily known, is a small sexually immature nematode, usually found lodged within capsules or cysts, and occupying the muscles of some animal, such as the pig, or of man himself. When the little worm is removed from the cyst its entire length will be found not to exceed the 1/20th of an inch. In its full-grown or sexually mature state it is still a very minute worm; the males measuring only the 1/16th of an inch, whilst the females, which are more than as large again, reach up to about 1/8th of an inch.
The professional importance of the trichina more directly concerns the medical man than the veterinarian; nevertheless, since the human disorder termed trichiniasis takes its origin from the consumption of animal food, especially pork, it is clearly the duty of the latter to understand the nature of the malady thus provoked, and to acquaint himself with the phenomena of the parasite's development. The experiments of various helminthologists, and especially those of Davaine, have distinctly proved that when small animals, such as rats, rabbits, and cats, are largely infected, they, like man himself, readily succumb to the disease. In the case of larger animals, a very great amount of infection is necessary to give rise to any external symptoms. So complete, indeed, does this immunity appear to be, that a pig experimented on at the Royal Veterinary College showed no sign of the disorder, although from subsequent post mortem evidences it was calculated that its flesh contained sixteen millions of living worms.

Until very lately we flattered ourselves that in England and Scotland there was no such thing as trichina existing in our home-reared porkers; but so far as the former division of the country is concerned, this immunity can no longer be said to exist. Not only have several English fed pigs been found to harbour spiral flesh-worms, but in the year 1871, as recorded by Dr. Dickenson, an outbreak of trichiniasis occurred in a farmer's family in Cumberland, this attack resulting from the consumption of pork reared by themselves. As Mr. Gamgee has well remarked, "If pigs are permitted to swallow the germs of human parasites, as in Ireland and in many British piggeries, we must expect hams, bacon, and pork sausages to be charged with the embryonic forms of human enzootia." Very much more, of course, might be said on this subject in relation to questions of hygiene; but our object in these pages is merely to show the necessity of a general acquaintance with the subject.

The symptoms, whether occurring in man or animals, are generally believed to be due to the wounds and consequent irritation set up by the worms during their wanderings in the tissues of the host; but whilst this is true as a cause of the phenomena occurring in the second stage of the disease, it is obvious that the earliest symptoms, often accompanied with diarrhea, are due to intestinal irritation alone. Some authors
have, indeed, contended that there is no such thing as traumatic injury caused by the wandering parasites, but our best experimentalists in helminthology are one and all in favour of the view here advocated.

Whilst many admirable memoirs have been written on the structure and development of trichina (the literature of the subject being of very great extent), we have on the whole satisfied ourselves that the clearly enunciated statements and conclusions of Leuckart are worthy of every confidence. The following is a brief résumé of his conclusions, given almost in his own words:

1. *Trichina spiralis* is the juvenile state of a little round-worm.
2. The mature *Trichina* inhabits the intestinal canal of numerous warm-blooded animals, especially mammals.
3. The intestinal *Trichinae* attain sexual maturity on the second day after their introduction into the stomach.
4. The eggs are developed within the parent worm into microfilaria-like embryos, which are born free from the third day onwards.
5. The new-born young soon commence wandering, passing the intestinal walls, and passing directly through the abdominal cavity into the muscles of the host.
6. The directions in which they proceed were in the course of the intermuscular connective tissues, the majority of the embryos resting in the muscles of the abdomen and thorax.
7. The embryos penetrate the separate muscular bundles, and at the expiration of fourteen days they will have acquired the size and organization of the spiral flesh-worm.
8. Soon after the intrusion of the parasite the infected muscular fibre loses its original structure; and after a while the spot occupied by the rolled-up entozoa becomes spindle-shaped, within which the well-known lemon-shaped cysts are formed.
9. The further development of the muscle trichines is altogether independent of the formation of these cysts, the walls of which become hardened by calcareous deposition and thus, moreover, males and females are already distinguishable in the larval state.
10. The immigration of the young parasites in large numbers
produces very serious or even fatal consequences; and thus it happens, that in proportion to the quantity of imported parasites the symptoms resulting will be either severe, dangerous, or even fatal.

It has been stated by some writers that even pigs occasionally display symptoms of trichiniasis, the signs of the disease in the animal being loss of appetite, quiescence, aversion to all kinds of movement, and even partial paralysis of the limbs. In the human subject it is well known that the symptoms are much more severe, many of the patients enduring the most intolerable agony, until at length death mercifully comes to put an end to their sufferings.

Here it will not be out of place to mention that cats are liable to be affected with another disease very closely resembling trichiniasis, which may appropriately be called olulaniasis. The disorder is occasioned by a minute trichina-like nematode termed by Leuckart Olulanus tricuspis. It gains access to the lungs in the larval state, producing death by suffocation.

Our knowledge of the history of the development of the larger round-worms is very incomplete; nevertheless the causes of the prevalence of these worms in particular localities and during certain seasons are not far to seek. It is clear that their final stage of growth is accomplished with great rapidity, otherwise we should not meet with lumbricoids in pigs and puppies scarcely three weeks old. Large round-worms have also been found in very young colts. The ordinary lumbricoids of the horse, of the pig, and of man, so very closely resemble each other, that by some they are regarded as mere varieties of one species (Ascaris megaloccephala, A. suilla, and A. lumbricoides). Whether they are so or not is of little practical moment, for it seems quite certain that a perfect knowledge of the earlier stages of development of any one of them would furnish a clue as to what obtains in the others. It is probable also that the lumbricoids of the dog and cat undergo similar changes.

The eggs of the common round-worm have been kept alive by Davaine for more than five years; and various observers have watched their development in fresh water up to the stage of imperfectly developed embryos, and have kept them alive in this condition for three months.
Dr. Davaine administered some of his five-year-old embryos to rats, and had the satisfaction of finding a few of their eggs in the faeces, with their embryos still living, and striving to get out of the shells. He administered others to a cow, also introducing some into the stomachs of dogs in small linen-covered flasks. As a general result, it may be said that the embryos escaped from their shells; but the contents of those eggs in which the process of yolk-segmentation had not arrived at the stage of embryonic formation remained undigested. So far back as the year 1853 Verloren reared embryos in the eggs of the dog’s round-worm within a period of fifteen days in distilled water. Dr. Cobbold has also reared the embryos of this species (Ascaris marginata) in fresh water, and has kept them alive for a period of seventeen months. At the expiration of this period, and during the warm weather, some of them escaped from their shells.

According to Davaine, the eggs of many nematodes will readily retain their vitality though long exposed to dryness, but their contents will not go on developing during this period of exposure. In the case of Ascaris tetraperta of the mouse, however, embryonic formation goes on in spite of the absence of external moisture. He has noticed the same thing in the oxyurides of rodentia. Dryness does not even destroy the eggs of Ascaris lumbricoides and Trichocephalus dispar. It would seem, in short, that the eggs of nematodes, which normally take up their residence in cats, dogs, and carnivorous animals which reside in arid regions, will develop embryos in ovo without a trace of moisture. Davaine is of opinion that it is not necessary that nematode embryos should pass through the body of any intermediary bearer; and he believes that they are often directly transferred to the stomach of their appropriate hosts whilst adhering in the condition of an impalpable dust to the coats of their bearers, whence they are detached by the animals themselves when licking the fur. With the eggs of Ascaris megalolechala Dr. Cobbold has performed several experiments, having reared the embryos in simple fresh water, and found them capable of escaping from their shells during warm weather. He also succeeded in rearing these larvae in pond mud, noticing at the same time that after their exclusion they grew more or less rapidly up to a certain point, after which they appeared to stop, as if waiting transference to some host for the further accom-
plishment of their larval growth. The addition of horse-dung to the soft wet mud in one case, and of cow-dung in another, neither appeared to advance nor retard the process of embryonal growth so long as the embryos remained in their shells. On the other hand, when the embryos were reared in simple horse-dung, purposely kept moist, they attained a higher degree of organization than did those which were reared in water and wet mud. Having watched hundreds of these larvae under varying conditions, Cobbold came to the conclusion that after their escape from the egg, their growth, strength, and activity are favoured, if they happen to have gained access to fluid media containing impurities. Ditch or muddy pond water would appear to be eminently favourable to the development of the escaped larvae up to a certain stage of growth.

That warmth is eminently favourable to the development of all kinds of parasites is a well-established truth; and in the case of most nematodes it appears to be absolutely essential to the formation and hatching of the embryos. Take the case of Oxyuris, for example. As Leuckart observes (Die Menschlichen Parasiten, Bd. ii. a. 326), “One only needs to expose the eggs of the human thread-worm to the action of the sun’s rays in a moistened paper envelope, when in five or six hours the tadpole-shaped embryos become slender elongated worms, which are not unlike the sexually mature oxyurides in form, exhibiting rather lively movements under the influence of the warmth.” The power of warmth is thus very obvious in the case of oxyuris, since without a certain degree of temperature the earliest embryonal change cannot be accomplished. As in the oxyuris of man, these early changes are sometimes accomplished whilst the eggs, discharged from the maternal worm, still lie in the feces or rectum of the bearer; so also it is probable that similar changes occur in the eggs of Oxyuris curvula whilst they still remain in the rectum of the horse. According to Leuckart, the escape of the embryos of the human oxyuris ordinarily takes place when the eggs are swallowed by a new human bearer; but from the observations of Heller, it is also quite certain that any person may infest himself by swallowing the eggs which have come from oxyurides dwelling in his own person. In either case the escape of the embryos from the egg is brought about by the action of the gastric juice acting upon the egg-shell. The
further changes resulting in the formation of the perfectly mature oxyuris are accomplished within the alimentary canal of the bearer. Here we have cases in which the adult sexual form of the parasite lays eggs in the alimentary canal of its host. Favoured by the warmth and moisture of the alimentary canal, the embryo reaches a certain stage of development while still enclosed within its egg-shell. If these eggs, expelled with the feces, reach a new host, the embryo is hatched, and develops into a sexual adult. This is the mode of development in *Trichocephalus affinis*, and almost certainly in *Oxyuris vermicularis* of man, *Oxyuris curcula* of the horse, and *Ascaris lumbricoides*.

Thus Dr. Heller found, *post mortem*, young round-worms, of the species *Ascaris lumbricoides*, in the intestines of an imbecile. There were eighteen specimens, the largest of which had only acquired the length of about half an inch, whilst the smallest gave a long diameter of only 2.75 millimetres, or let us say roughly the ninth part of an inch. Thus Heller, in part at least, bridged over the gap which had formerly existed between the size of the embryo at the time of expulsion from the egg and the large sized ones which alone had been formerly observed in the alimentary canal, and in this case we are almost certain that the eggs are hatched in the alimentary canal, where the embryos attain sexual maturity.

The mode of development is usually slightly different in *Ascaris* and *Strongylius*, where the eggs have a thin shell, and the embryo enjoys for a time a non-parasitic existence in water or mud. Here it grows in size, but develops no sexual organs. Sometimes it accidentally attaches itself as a parasite to a freshwater mollusc, but it undergoes no change there. Eventually, gaining access to a proper host, it reaches sexual maturity, and the cycle of its life is repeated. This is the mode of development of *Dochmius trigonocephalus* of the dog, of *Dochmius duodenalis* of man, and of various species of *Acaris*, e.g., *Acaris acuminata* of the frog. In the case of some of the strongyles, there can be no doubt that the earlier larval transformations are undergone after the eggs have been expelled and lodged within soft soil or mud. Leuckart has proved this in the case of *Strongylius hypostomus*, whose rhabditiform young cast their
first skin in about three weeks, at which time, as happens with many other larval nematodes, they part with their tails.

The case is still more complicated when the nematode requires two hosts to complete its metamorphosis. In some cases it is the egg which is taken into the first or intermediate host, in other cases it is the larva. We have a good example of a parasite requiring two hosts in the case of the *Spiroptera obtusa* of the mouse. The eggs pass out of the alimentary canal of the mouse, and are eaten by the meal-worm. The eggs are hatched, and the larva, after living in the meal-worm for about five weeks, forms round itself a capsule of connective tissue. If meal-worms containing these encysted larvae are eaten by mice, the larva leave their capsules and become the sexually mature *Spiroptera obtusa* of the mouse. The *Filaria sanguinis hominis*, or *Filaria Bancrofti*, is another good example of a parasite which requires two hosts. The sexually mature worm is found in the human tissues, and is viviparous, producing numerous larvae, which make their way into the blood. The blood is sucked by mosquitoes, and thus the larvae get into the mosquito, where they increase in size, and undergo various changes. When the mosquito dies the larvae pass into the water and live for a time a free life. Ultimately they gain access to the intestines with the water, and, boring into the tissues, produce again the larvae on attaining sexual maturity in their human bearer.

A third example of a nematode requiring two hosts is the *Trichina spiralis*. The sexually mature worm lives in the alimentary canal, and is viviparous, producing numerous larvae, which make their way out of the alimentary canal into the muscles, where they encyst. When flesh containing the sexually immature larvae is eaten, the cystic stage comes to a close, and sexual maturity is attained in the alimentary canal, where the larvae are again produced.

The eminent Russian traveller Fedtschenko observed the primary larval changes to take place in the young of the guinea-worm during their sojourn in the alimentary canal of *Cyclopes*, these entomostracous crustaceans being destined to play the part of intermediary bearers. In like manner, there can be little doubt that the young of the strongyles, which occasion husk and lamb disease, undergo their primary changes of de-
development either within soft mud alone, or within the bodies of small slugs and other minute denizens of herbage, or possibly within the bodies of larval insects and minute entomostreemata, inhabiting ponds, ditches, and running streams. It thus seems that whilst some nematodes can accomplish their developmental processes without any lengthened sojourn outside their final bearer, others, on the contrary, require particular, varied, and prolonged conditions which shall enable them to undergo certain preliminary changes altogether exterior to and apart from the bodies of their ultimate hosts. In short, as Leuckart points out, we have two distinct groups of strongyles: those which lead a free life in their larval state, undergoing a certain grade of development in mud and water; and those which pass through certain larval changes of growth within the bodies of insects and other intermediary bearers.

So much for the natural history of the nematoda, or order of thread-worms and round-worms, on which much more might be said, were we not limited to a general view of all the groups of internal parasites. As it is, the reader will not fail to perceive that, speaking generally, it is now clearly understood how cattle and sheep and other animals obtain one frequent form of lung disease. It is almost needless to add that the labours of helminthologists have thus contributed largely towards the formation of rational principles on which to base successfully both a radical and prophylactic method of treatment.

**Platyhelminthes.**

The flukes and tape-worms which belong to this class have flattened bodies, hence the name *Platyhelminthes* or flat-worms. They are hermaphrodite, and are usually furnished with organs of attachment, such as suckers and hooks. Usually there is an alternation of generations, i.e., the young one is not like its parent, but must pass through various metamorphoses in order to reach the adult form.

**Trematoda.**

This order comprises the flukes; and it is of great interest to the veterinarian, inasmuch as he is occasionally consulted in
reference to the well-known disease in sheep termed rot. This
disorder is unquestionably due to the presence of the common
liver fluke (D Digona hepatica), a parasite that is seldom more
than an inch in length. Other animals than sheep are liable to
be infested by it, but, except in the case of cattle, hares, and
rabbits, it only very rarely occasions severe disease. In about a
score of instances this entozoon has been detected in the human
body. It sometimes also infests the horse.

For many years past investigations have been conducted with
the special purpose of ascertaining the manner in which cattle and
sheep infest themselves with this parasite; and although we
have not succeeded in tracing out all the stages of growth of the
common fluke itself, researches amongst the trematodes generally
have enabled observers to arrive at conclusions of the highest
practical importance. Intelligent cattle-breeders and agricul-
turists have all along observed that the rot was particularly
virulent after long-continued wet weather, and more especially
so when there had been a succession of such seasons; and
further, that the flocks grazing in low pastures and marshy
districts were much more liable to invasion than those which
pastured on higher and drier grounds; but, what is most
interesting, they also observed that an exception occurred
in the case of those sheep feeding in the extensive salt
water marshes bordering our eastern shores. It was probably
this latter circumstance which suggested the common and
useful practice of mixing salt with the food of sheep and cattle,
both as a preventive and curative agent. At all events, as will
appear in the sequel, the intelligible explanation of the good
effected by this simple practice, is intimately associated with a
correct understanding of the mode of development of the parasite
in question.

The symptoms, treatment, and pathological appearances con-
ected with rot are not here discussed, the present chapter
being limited to the natural history of the entozoa. Even
within this limitation the subject is too large to be treated
of exhaustively and in detail; but for all practical purposes
it is probably sufficient to follow the plan we have adopted
in the case of trichina, namely, to offer a series of conclusions,
such as appear to be well established by the independent re-
searches of various helminthologists. In this connection it is
only necessary to add that the labours of Steenstrup, Lechat, Van Beneden, Pagenstecher, Moulinie, Davaine, Filippi, and Simonds have played a most conspicuous part. It may also be observed that, notwithstanding many assurances to the contrary, the present state of our knowledge does not justify our going beyond the data and conclusions here given. The statement made by one naturalist, to the effect that the larvae of the common fluke reside in the mollusc called *Succinea pura*, has not received confirmation. That the larvae are not limited to a single species of molluscan bearer is, to say the least, extremely probable. All things considered, perhaps the following may, in the present state of the science, be regarded as a fair exposition of the genetic relations and phenomena exhibited by the common liver fluke.

1. The liver fluke, in its sexually mature state (*Dicrocoelium hepaticum*) gives rise to the disease commonly called rot; this affection being also locally termed coache (Dorsetshire, Devon), iles (Cornwall) and bane (Somersetshire). In France it is known as the *Cachexie aquæuse*, and more popularly as *pourriture*. In Germany the epidemic disease is called *Fäule*, and in a more limited sense either *die Fäule* or *die Leberkrankheit*.

2. The rot is especially prevalent during the spring of the year, at which time the fluke itself, and innumerable multitudes of the free eggs, are constantly escaping from the alimentary canal of the bearer. The germs are thus ordinarily transferred to open pasture-grounds, along with the feces of the bearer.

3. As it has been shown by dissections that the liver of a single sheep may harbour several hundred flukes, and as also a single adult fluke is capable of throwing off several thousand eggs, it is certain that any rot-affected flock is capable of distributing millions of fluke germs in the egg condition.

4. Such flukes as have accidentally escaped their host *per anum* do not exhibit powers of locomotion sufficient to enable them to undertake migrations. Their slight movements, however, subserve the purpose of concealing
them in the grass where they have fallen, and also, probably, aid in the further expulsion of eggs, which latter can only pass from the oviduct in single file, one at a time.

5. After the death of the escaped flukes, the further dispersion of the eggs is facilitated by the subsequent decomposition of the parent worm, and also by its disintegration, occasioned by the attacks of insects. It has been calculated that the uterus of a full-grown fluke may contain upwards of forty thousand eggs.

6. By the agency of winds, rains, insects, the feet of cattle, dogs, rabbits, and other animals, as well as by man himself, the freed ova are dispersed and carried to considerable distances; and thus it is that a considerable proportion of them ultimately find their way into ponds, ditches, canals, pools of all kinds, lakes and running streams.

7. The eggs at the time of their expulsion exhibit the already segmented yolk in a state of fine division. The egg contents continue to develop outside the parent's body; the granular matrix finally becoming transformed into a ciliated embryo, which, when set free, follows the habit of infusorial animalcules in general by swimming rapidly in the water. The escape of the embryo is effected at the anterior pole of the egg-shell, which is furnished with a lid that opens in consequence of the action of prolonged immersion, aided by the vigorous movements of the contained embryo.

8. The ciliated, free, swimming embryo of the common fluke, at the time of its birth, exhibits the figure of an inverted cone, its anterior extremity, which is broad and somewhat flattened, supporting a central proboscis-like papilla. A small pigment spot, placed dorsally, and having the form of a cross, is supposed to be a rudimentary organ of vision. After the lapse of a few days the cilia fall off, the embryos then assuming the character of planaria-like creeping larvae.
9. Notwithstanding its abridged locomotive powers, the non-ciliated larva sooner or later gains access to the body of an intermediary bearer, within whose tissues it becomes transformed into a kind of sac or sporocyst. In this condition the larva is capable of developing other larvae in its interior by a process of budding. The sporocysts vary in character, and when highly organized are called rediae; they are often also called nurses; the latter term being generally applicable to all forms of trematode larvae which reproduce by internal budding.

10. The progeny of the more highly organized "nurses" (sporocysts or rediae) are furnished with tails, in which characteristic stage of growth they constitute the well-known cercariae or higher trematode larvae. In this stage they migrate from their intermediary molluscan hosts, and pass into the water to lead for a time an independent existence.

11. There is every reason to believe that before the cercariae succeed in gaining access to their final or definitive hosts, they re-enter the bodies of molluscs or aquatic insects. This they accomplish by means of a boring apparatus; and, having previously cast off their tails, they encyst themselves beneath the surface of the skin. In this new situation they acquire a still higher degree of organization, thus realising the so-called tailless or pupa stage.

12. The pupae or encysted cercariae are at length passively transferred, along with its fodder or its drink, into the digestive organs of the ultimate host; and it is thought that the cysts serve the purpose of a protective covering until the larvae have passed into the true digestive stomach, in which organ the action of the gastric juice, by dissolving the sac, liberates the pupa.

Footnote: From the investigations of Mr. Thomas, it is assumed that the intermediate host of the liver fluke is not the slug as supposed, but a small aquatic animal which has hitherto been overlooked, or that the roots of grasses play the part of host in the larval forms of digenetic trematodes.—(Veterinarian, April 1882.)
TREMATODA.

From the stomach the tailless larvae succeed in entering the common liver duct and its branches, in which situation they rapidly acquire all those internal organs which characterise the adult flukes. In this way the life cycle is completed.

From the researches of Van Beneden, and especially also of Pagenstecher, it would further appear that the degree of multiplication of the larvae and the extent of their organization are largely affected by varying states of the season, in association with other co-ordinating external conditions. This conclusion is important practically. For example, the highly organized germ-sacs or sporocysts (rediae) are capable, under favourable climatal states, of developing not only the ordinary tailed cercariae in their interior, but also new germ-sacs? It would seem, further, that there is no recognisable limit either to the variety or to the extent of larval fluke development. No wonder, therefore, that an accidental concurrence of favourable conditions, such as happens in particular seasons, should be followed by the disastrous outbreaks recognised as epidemics of rot. As we cannot regulate the character of the seasons, so neither can we prevent the occurrence of many epizootics. Helminthological science, however, does enable us to lessen the amount of disease, by affording an adequate insight into the nature of the causes concerned in its production. We may, indeed, yet be able to ascertain with precision what intermediary bearers are immediately concerned in the harbouring of the cercarican or pupal representatives of the common fluke; and should these guests be found to reside in the body of some one particular and readily accessible mollusc, it is obvious that the collection and destruction of the intermediary bearer in question would operate to limit, if it did not, in course of time, altogether serve to eradicate the disease.

Guided by indications of the order just mentioned, Dr. Rowe, of Mount Battery, Goulburn District, Victoria, has proposed a somewhat rough and ready method of stamping out the rot, which disease, by the way, appears to be far more constant as an epizootic in Australia than it is with ourselves. In brief, the plan suggested was to burn the whole of the grass where
rot-affected sheep have been pasturing, to destroy the diseased animals themselves, and, after a time, to restock with sound animals.

There can be little doubt that this method would prove effective for a while; but since, to insure a permanent result, a frightful sacrifice would have to be made in the first instance, it is to be feared that the experiment could not be undertaken without severe and rather unconstitutional legal enactments. Moreover, supposing the colony were rendered entirely free from rot, the original exciting cause, which we are told brought the malady into the country somewhere about the year 1855, might again reintroduce the disorder. On this subject, however, the reader will do well to consult the notice of Dr. Rowe’s observations, as recorded in the *Veterinarian* for February 1873. In perusing the communication in question, it should be borne in mind that the observations proceed from the pen of an observant and extensive stock-owner.

**CESTODA.**

This natural order of flat-worms has acquired its name from the circumstance that most species in the adult condition resemble a tape or band, hence also the common name tape-worm. Sometimes, however, the resemblance to a tape fails altogether, as is conspicuously the case with the little tape-worm of the dog (*Taenia echinococcus*). The absence of a mouth and an alimentary canal are very characteristic of the order, so that in the tape-worm we have an animal feeding by the process of osmosis.

If an adult tape-worm be examined we find that it consists of segments. The anterior segment is differently constructed from all the rest, and is variously designated as the head, *soma*, or *scolex*. Behind the anterior segment or head follows a chain of segments for reproductive purposes, the *generative segments* or *proglottides*. These generative segments are produced by a process of budding from the head. In the same worm we find them at all stages of development, unripe, half-ripe, or completely ripe segments, the youngest nearest the head. It is quite important to observe that the head produces all the rest of the worm by a process of budding, so that if all the body be
removed and the head left behind, the worm will be again reproduced.

The head or scolex, in addition to its power of continually budding off chains of segments, is provided with organs by means of which it fastens itself to the wall of the alimentary canal. These organs of attachment in the Bothriocephalus take the form of two longitudinal grooves, hence the name, while in the Taenia the sides of the head are provided with four sucking discs. In addition to the four suckers, some tape-worms (Taenia armata) have circles of hooks anterior to the suckers, each hook formed in a little pocket. These hooks have sharp projecting points, which serve as anchors for the tape-worm. Their presence or absence, their size, form, and number, are often very characteristic, and their examination is often facilitated by the use of caustic potash, in which the hard chitinous material of which they are composed is insoluble.

Following the head come the youngest segments, as yet narrow and short, and not plainly distinguishable from one another, often spoken of as the neck. Proceeding backwards from the neck, the segments become broader and longer, and more distinct from one another. The hindmost segments have reached the full size, are capable of separating from the others, and can even have an independent existence for a time. Ultimately these detached segments wander out of the body, or are expelled with the feces, when they die and decay; but the ripe eggs provided with their hard shells retain their vitality, and are ready, under favourable conditions, to undergo a series of metamorphoses, whose final term is the adult tape-worm.

Each segment is provided with a complete set of male and female reproductive organs, so that, if we take into account the fact that the segments can detach and lead for a time an independent existence, we may regard each segment or proglottis as a complete hermaphrodite individual. In the youngest segments the sexual organs are not yet developed, but in the half-ripe segments the male and female organs are distinguishable, whereas in the completely ripe segments the uterus loaded with its eggs is the conspicuous part. The form of the uterus of the ripe segment is very characteristic, and may be readily observed by pressing the ripe segments between two slips of glass, and examining with the naked eye or a pocket lens. For example, in
the *Bothriocephalus* the uterus has the form of a rosette, whereas in the *Taenia* it is usually tree-like, and by counting the number of uterine branches we are often able to determine the species. At the same time the sexual openings can be observed—(1.) On the margin, and alternately right and left, i.e., on the left margin of one segment, on the right margin of the next, on the left margin of the third, and so on, e.g., *Taenia caninum*, *Taenia serrata*, *Taenia marginata*, and most *Taenia*; (2.) Two marginal openings for each segment, one on the right margin and one on the left (only in *Taenia cuvermerina* and *Taenia expansa*); (3.) Openings not marginal, but in the middle of the ventral surface, e.g., *Bothriocephalus*.

If the eggs from the uterus of a ripe segment of a *Taenia* be examined, they appear to the naked eye as coloured points and under the microscope as round or oval bodies. The shell is thick, and is seen to consist of little prisms cemented together. In the interior of the shell the embryo is visible as a little solid body provided with six hooks. The eggs of the *Bothriocephalus* present quite a different appearance.

These eggs are hatched when they gain access to the alimentary canal of a suitable host, which is rarely the same as the host of the adult *Taenia*. Stimulated by the warmth and acted upon by the gastric juice of the alimentary canal, the shell is more or less dissolved, and the six-hooked embryo or Proscolla becomes free. Helped by its hooks, the embryo bores its way through the wall of the alimentary tract, and is carried along with the blood, or otherwise, to some place suited for its further development, it may be the connective tissue, muscles, liver, lungs, or even the brain, as is the case with the *Cestrum cerebralis* in the brain of sheep. Having reached a suitable resting-place, the solid embryo drops its hooks, and, acting as a foreign body, causes local exudations and new formations of granular matter and connective tissue. Thus the surrounding tissues form nutritive material and a connective tissue capsule for the solid embryo. The embryo, fed at the expense of the surrounding tissues, rapidly grows in size, loses its solid character, and becomes a hollow sac filled with fluid. In this condition the creature is spoken of as a cystic or bladder-worm, or more commonly as a measles or hydatid, and this cystic stage is quite comparable with the sporocyst of a trematode-worm. The cystic-
worm, still enclosed in its capsule, undergoes further important changes. At one or more points in its wall a process of budding takes place, each bud growing inwards in the form of a hollow pocket, in the interior of which the suckers, or suckers and hooks, are developed. Each bud has now the form of an invaginated tape-worm head, and when evaginated is quite like that of the adult tape-worm, differing mainly from it in being hollow.

In other cases the cystic-worm undergoes more complex changes, the buds developing not into tape-worm heads, but into secondary cysts, while the buds on the secondary cysts become the tape-worm heads, as is the case in *Echinococcus* cysts.

These different kinds of cystic-worms, which are merely the larval stages of tape-worms, have received different names.

1. *Cysticercus*—cyst filled with serum, and provided with only one head.
2. *Cysticercoid*—cyst without serum, only one head.
3. *Cienurus*—cyst filled with serum, and provided with many heads.
4. *Echinococcus*, primary cyst, gives rise to secondary cysts filled with serum, each secondary cyst producing numerous heads.
5. *Acephalocyst*, without heads.

Thus the tape-worm egg, when hatched, gives rise to a six-hooked embryo, the six-hooked embryo changing into a cystic-worm, with one or more tape-worm heads, and that is the end of one part of its development.

The cystic-worm having developed its heads, can remain for a length of time without undergoing further change, cases being known in which human beings have carried an *Echinococcus* cyst for over thirty years. But if flesh, lung, liver, or brain containing cystic-worms be eaten by certain animals, then a new course of development begins. The head of the young worm comes out of the cyst, which is digested by the gastric juice, the head being protected from the action of the juice by the carbonate of lime with which it is loaded. The head is now free, attaches itself to the intestinal wall, and begins rapidly to form a chain of segments, which develop their sexual organs and their eggs, and thus we have now the cystic-worm changed into an adult *Taenia*,
with its head and segments. The ripe segments containing the eggs detach and get out of the body, and now the eggs are again ready to commence anew their life cycle.

The development of the *Bothriocephalus* differs in several respects from that of the *Taenia*. The egg-shell is provided with a lid. In its interior the embryo is formed, the outer layer of cells forming the ciliated coat, and the central mass of cells the six-hooked embryo. The ciliated embryo comes out of the shell by the opercular aperture, and by means of its cilia swims about in the water. Experiments have shown that the embryos of *Bothriocephalus latus* can develop into a sexually mature worm without passing through a cystic stage. The eggs were taken and kept for six months in fresh water till the embryos were formed. A very young pup was supplied with milk containing these eggs and the ciliated embryos. On the 10th July the pup was fed with the eggs, and on the 25th August it passed *Bothriocephalus latus* 42½ cm. long,—that is, about 17 inches. On the 9th September it was killed, and three *Bothriocephalus* were found in its intestines.

Interesting as are the phenomena connected with the origin and development of the various tape-worms found infesting our domesticated animals, it is not necessary for the practitioner of veterinary medicine to acquaint himself with the natural history details of all the forms which are apt to come under his notice: nevertheless he will find it useful to have a general knowledge concerning some of them. Thus, he should know that no less than six different kinds of tape-worm infest the dog. Of these he should be further aware that one (*Taenia serrata*) is acquired by swallowing the larvae (*Cysticercus pisiformis*) which reside in the bodies of rabbits and hares; that another (*Taenia marginata*) is obtained by devouring the larvae (*Cysticercus tenuicollis*) which reside in the viscera of the sheep and pig; that another (*Taenia caenuirus*) is obtained by ingesting the larvae (*Cranurus cerebralis*) which infest the brains of sheep and other animals; that another (*Taenia echinocestus*) is developed when the dog swallows the larvae (*Echinococcus veterinorum*) found in the viscera of various animals, especially the pig; and lastly, that yet another (*Taenia cucumerina*) results from swallowing the dog louse (*Trichodectes latus*), which harbours its representatives cysticercus or measles.
To describe minutely all the changes through which these and other tape-worms allied to them pass, would require a separate treatise. We are concerned chiefly to present a general view of the subject; and, perhaps, in further illustrating the phenomena of tape-worm life, we cannot do better than select that particular species which, in its larval state, gives rise to the familiar disease, variously termed vertigo, gid, staggerers, and sturdy.

Practical veterinarians have repeatedly asked in what manner sheep become affected with gid. For them it is not sufficient to be told that the sheep obtains the worms from the dog on the one hand, and that the dog in its turn obtains tape-worm from the sheep. There are, as we have seen, several tape-worms liable to reside in the dog, and only one of these cestodes is concerned in the matter at issue, and that is the *Tania cœnurus*.

If the head of a yearling affected with gid be opened, one or several hydatids will be found in the brain. These hydatids must not be confounded with the common and often much larger hydatids found in the viscera of various animals, nor with the slender-necked hydatids liable to infest the abdomen of the sheep. The brain-hydatids in question are cœnuri, being readily recognised by their polyccephalous character; that is to say, they are furnished with numerous processes termed heads. The full-grown gid hydatid is always lodged within a sheath or cyst, and when removed, whether by operation or post mortem, invariably displays these heads at the surface. To the naked eye, indeed, the heads may merely exhibit the appearance of minute whitish granulations, especially if they happen to be inverted and retracted within the walls of the hydatid. The cœnurus otherwise presents the general appearance of an ordinary bladder-worm, containing in its interior a clear, amber-coloured, watery fluid.

On subjecting the so-called heads to microscopic examination, they will be found to display a double crown of minute hooks in front, besides four sucking discs, such as are commonly seen on the head of an ordinary tape-worm. A single large cœnurus may support several hundreds of these heads; each head in reality representing a young tape-worm. This relationship has been proved by experiment. If, for example, a fresh cœnurus be given to a dog, each of the hundred or more heads becomes con-
verted into a tape-worm, having characters quite distinct from all the other tape-worms that are liable to infest the dog. About eleven weeks would be necessary for the tape-worm to assume its perfect or sexually mature condition. Thus, in one experiment, where only five days were allowed to elapse before the canine bearer was killed, the heads were found alive, and separated from the hydatid, but displaying no trace of any body. In a second experiment, where three weeks elapsed, the young and sexually immature tape-worms had only attained the length of one inch and a half. In a third experiment, where the interval extended to two months, the tape-worms had acquired a length of eighteen inches; but the eggs, even then, were not perfectly developed.

A period of three months being somewhat more than sufficient for the maturation of the gid tape-worm, the perfect ova will by this time be found escaping from the dog along with its feces. These eggs, in common with those of other tape-worms, display six-hooked embryos in their interior. Wherever the infested dog wanders and passes excrement per anum, there will it be privileged to distribute the ova. The eggs, if left to themselves, would do no harm; but by various agencies they are further distributed over the pastures where yearlings and sheep are grazing. Millions of tape-worm germs are thus annually scattered far and wide. In due course the ova are swallowed by grazing animals. When the ova have arrived within the true digestive stomach, the gastric juice dissolves the shells, and the minute six-hooked embryos forthwith make their escape. They speedily set about migrating on their own account; and having, by means of the hooks in question, bored their way into the blood-vessels, they are carried to and fro in the current of the circulation. By virtue of some selective capacity they seem to know when they have arrived within the vessels of the brain, in which organ, after escaping the vessels, they bore their way to the final resting-place. Here, by a process of transformation, they part with their hooks, and gradually acquire the bladder-worm state, in which condition they vary in size from a pin's head to that of a large walnut. To attain the perfect polycelous state, they require a period of about ten weeks, and thus the whole cycle of development is accomplished within something like five months.
It must be allowed that the process of development above recorded is one of the most astonishing of all the biological phenomena with which the naturalist is acquainted. Not merely are the necessary changes of host remarkable, but the characteristics marking each phase in the life-history of the entozoan itself are still more noteworthy. At one time of its career the creature is a mere bladder-worm, at another an elongated tape-worm, at another a minute six-hooked embryo, and finally, once more, a bladder-worm. But this is not all; inasmuch as its development, in one very important particular, differs from the process undergone by the ordinary beef and pork tape-worms (Taenia mediocanellata and Taenia solium). Thus, whilst the egg of the common tape-worm is only capable of developing onward into a single sexually mature tape-worm, the solitary egg of the Taenia cancrus, as we have seen, becomes transformed into a multitude of tape-worms. In this respect, it is true, our parasite is, in some sense, eclipsed by another tape-worm that is resident in the dog (Taenia echinococcus); but, with this exception, we know of nothing comparable to it within the limits of cestode reproduction.

Amongst the other tape-worms of general interest to the professional man are those which are derived from the consumption of pork and beef. The meases of pork (Cysticercus cellulosae) are transformed into the Taenia solium, whilst those of beef (Cysticercus bovis) are transformed into the Taenia mediocanellata. These tape-worms, as such, are only known to infest the human body. The tape-worms of cattle and sheep, as well as those of the horse, probably all belong to that group of tape-worms whose larvae are normally resident in the bodies of insects and other non-vertebrated animals. This explains why their separate developmental histories have not hitherto been fully made out by helminthologists.

Those who desire further details on this head should consult the standard treatises of Leuckart and Kuchenmeister, and also Cobbold's manual of the parasites of our domesticated animals, in which the medical and sanitary importance of the beef tape-worm is dwelt upon at considerable length. Lastly, we desire to call particular attention to the fact that cysticerci or meases have been found in mutton. These small cystic worms are undoubtedly the representatives of a distinct species
of tape-worm that probably resides in the human bearer. Some account of the parasite (*Cysticercus oris*) is given in the supplement to Cobbled's larger treatise on *Entozoa* (p. 30), the self-same entozoon being much more recently and fully described by Dr. Maddox in the *Monthly Microscopical Journal* for June 1873.

We now know, therefore, that mutton and beef, as well as pork, may become measles; these three kinds of measles being perfectly distinct from each other, and all severally derivable from different species of tape-worm.

**ACANTHOCEPHALA.**

As already stated, this order of helminths is represented by a parasite which occasionally takes up its residence in the intestines of the pig. It is known as the large thorn-headed worm, or *Echinocephalus gigas*. The male commonly measures three or four inches in length; whilst the female often exceeds fifteen inches, examples having been recorded beyond two feet. The head is furnished with an armed proboscis, by means of which the worm anchors itself securely within the mucous membrane of the small intestines. This parasite is tolerably abundant in France and Germany, but very little is known of it in England. Professor Verrill, writing for the "Report of the Connecticut Board of Agriculture," speaks of this parasite as "the commonest and most injurious intestinal worm found in swine. These parasites," he adds, "not unfrequently perforate the walls of the intestine, and stray into other parts of the viscera, producing serious disease. Sometimes the intestine of a hog is found perforated by so many of these holes that it cannot be used in the manufacture of sausages. In severe cases the hogs are weak in the loins, and have the membranes in the corners of the eyes swollen, watery, and lighter coloured than usual. The excrement is hardened and highly coloured, and the animal often keeps up a continual squealing and grunting, especially in the morning. Such hogs are generally cross and morose, biting and snarling at their companions, but usually too weak to defend themselves if attacked in return, and easily thrown down. Finally, the weakness increases until the poor creatures are unable to walk about or to stand."
Although the development of the *Echinorhynchus* of the hog has never been fully traced, there can be little doubt that its mode of development is precisely similar to that known to occur in other members of the genus. Dr. Guido Wagener has furnished us with some admirable illustrations of the eggs and embryos of various species (Sieb. and Köll., *Zeitsch.* vol. ix.), but it remained for Leuckart to explain that these creatures during growth exhibit the characteristic phenomena of alternate generation (*Gött. Nachrichten*, 1862). His experimental investigations were chiefly made with *E. proteus* and *E. filicollis*. Professor Leuckart caused some fresh water crustaceans (*Gammarus*) to swallow the eggs of these small thorn-headed worms, and he had the satisfaction of observing that in a few days the embryos quitted their egg-shells and passed into the bodies of the unsuspecting intermediary bearers. After a series of further changes (which Leuckart regarded as comparable to those of a true alternate generation, and not simply metamorphic), the young parasites rapidly increase in size; the original skin of the embryo being cast off "as soon as the echinorhynchus occupies the whole interior of the embryo." The young parasites acquire sexual organs whilst still lodged within the intermediary bearers, so that, within about a week after they are transferred to the intestinal canal of their proper and ultimate piscine host, their development into the adult state is completed. What ordinarily takes place in the case of these echinorhynchchi of the fish must more or less appertain to the echinorhynchii of the hog. Swine, as we all know, are not very particular as to what they eat or drink, consequently they have abundant opportunities of swallowing insects, gammari, entomostracous crustaceans, or other minute creatures which are destined to harbour the larvae of acanthocephalous parasites.

According to Schneider the eggs of the *Echinorhynchus pigae* are discharged in the faces of the pig, which harbours the sexually mature adult. The eggs are devoured by maggots, and, reaching the stomach, are hatched. The embryos, which are provided with spines, bore their way into the body cavity of the maggot where they develop a young *Echinorhynchus* in their interior. The maggots are in turn devoured by the pig, in which the *Echinorhynchus* again reaches sexual maturity and produces ova.
DIPTERA.

As remarked at the commencement of this chapter, some of the flies are apt to prove troublesome as internal parasites. With those dipterous or two-winged insects which, as external parasites, occasion suffering to animals, we have here little or nothing to do; but since some of these forms of insect life play the double part of attacking their victims from within as well as from without, it is desirable to speak of such of them as fairly, in one phase of their life, come under the general class of internal parasites.

In this relation there is a particular group of insects that distinguishes itself above all the others. This is the so-called bot-producing family, comprising various forms of gadflies (Estridae).

As enemies of the horse, ox, and sheep, the gadflies have acquired notoriety from the earliest times. Thus they originally obtained their family title from the ancient Greeks, who called the gadfly of cattle the Oistros (Οἰστρος, from οἶσμεν, I impel; Latin (Oestrus).

When any person became unduly excited they said he had a fit of the Oistros. One can readily see the force of this expression after noticing how outrageously excited and furious a herd of cattle becomes when attacked by gadflies. As, however, it is not with the gadflies, viewed in the light of external enemies or parasites, that we have here to deal, we may dismiss this part of the subject by observing that, in the case of cattle, the gadflies have the ingenuity to select as their victims young beasts from two to three years old. The hide of an older beast is more difficult to pierce.

Since different species of gadfly attack different animals, and several kinds of fly, in the larval state, infest one and the same animal, it is desirable to speak of the forms belonging to our various domestic animals separately. In the first place we will consider those of the horse.

The common gadfly of the horse (Oestrus equi) attacks the animal whilst grazing late in the summer; its object being not to derive sustenance, but to deposit its eggs on the coat; and this it accomplishes by means of a glutinous material causing the ova to adhere to the hairs. The parts of the animal selected
are chiefly those of the shoulder, base of the neck, and inner part of the fore legs, especially about the knees; for in these situations the horse will have no difficulty in reaching the ova with its tongue. When from any cause the animal licks those parts of the coat where the eggs have been placed, the moisture of the tongue, aided by warmth, hatches the ova, and in something less than three weeks from the time of the deposition of the eggs, the larvae thus make their escape. As maggots, they are next transferred to the mouth, and ultimately to the stomach of the equine bearer along with food and drink. Of course a great many larvae perish during this passive mode of immigration; some being dropped from the mouth, and others being crushed in the fodder during mastication. It has been calculated that out of the many hundreds of eggs deposited on a single horse, scarcely one out of fifty of their contained larvae arrive within the stomach. Notwithstanding this waste, we are all of us familiar with the circumstance that the interior of an animal's stomach may become completely covered with the larvae in the condition of "bots." Whether few or many, they are retained in this singular abode chiefly by means of two large cephalic hooks, which are inserted into the mucous membrane.

As soon as the bots have attained their perfect growth, as such, they voluntarily loosen their hold, and allow themselves to be carried along the alimentary canal until at length they make their escape with the faeces. It is said that during their passage through the intestinal canal they not unfrequently re-attach themselves to the mucous membrane, thereby occasioning severe intestinal irritation. When thus lodged in the neighbourhood of the anus they seriously inconvenience the animal. In all cases, however, they sooner or later fall to the ground. When once transferred to the soil they bury themselves beneath the surface in order to undergo the change whereby they are transformed from the bot state into the pupa condition. At length, having remained in the soil for a period of six or seven weeks, they finally emerge from their pupal envelope or cocoon in the active life-phase of the imago or perfect dipteron insect. It thus appears that these creatures in the form of bots ordinarily pass about eight months of their lifetime in the digestive organs of the horse.
That bots are capable of giving rise to severe disease in the horse there cannot be any reasonable doubt, but it is not often that the disorder is correctly diagnosed, since it is only by the passage of the larvae, or by their adherence to the verge of the anus, that the practitioner can be made aware of their presence. We are not called upon to dwell on this fact of the subject in the present chapter, but may remark in passing that Mr. J. S. Woods, V.S., has published in the *Veterinarian* a case of tetanus in a mare associated with the larvae of *Estrus equi*, and Mr. J. T. Brewer, V.S., has also given a case in the same journal, when the duodenum of a horse was perforated by bots.

Several other species of *Estrus* victimise the horse; one of the most formidable of these being the *E. hemorrhoidalis*. The fly is especially annoying in the initiatory stages of the attack, because, unlike the common species, it selects the lips and nostrils as the principal locality for the lodgment of the larva. According to Bracey Clark the mere sight of the insect produces extreme agitation, the horses wildly galloping to and fro in their usually vain endeavours to evade these winged tormentors.

The common bot-fly of the ox (*Estrus bovis*) passes through transformations similar to those undergone by the gadflies of the horse. It differs, however, in one important particular; for in place of acquiring its larval condition as a bot within the stomach, it takes up its residence for that purpose beneath the animal's hide. In this situation its presence gives rise to the formation of small tumours, termed *warbles*. The facts, in short are as follows:—Selecting, as before remarked, young beasts in good condition, the fly lights on the back on either side of the spine. The animal darts away in alarm, often bellowing furiously and frightening its companions. The whole herd forthwith rush about in a frantic manner; and it is said that the mere buzzing of the insects is sufficient to render yoked animals quite unmanageable. In a short time the insect succeeds in perforating the skin by means of an ovipositor, one egg being deposited in each opening. After a time the egg is hatched, and the young during growth produces sufficient inflammation to lead to the formation of the well-known *warbles*. Within the tumour the bot is placed with its head downwards, its tail being applied to a small external opening in the warble, in order that it may receive sufficient air for the purposes of respiration.
When the bots are mature they make their escape, and fall to the ground, burying themselves in the turf, or hiding underneath stones. During the process of metamorphosis the skin of the bot becomes transformed into a cocoon, and in course of time the pupa or chrysalis stage is completed. In this state it remains as a grub for a month or six weeks, at the expiration of which period the lid of the cocoon comes off, and the perfect insect or imago is set free.

The common bot-fly of the sheep (Estrus ovis) neither chooses the stomach nor the back of its bearer as a place of residence during its acquisition of the larval condition, termed the bot. This insect may be regarded as a worse tormentor than either of its common congener above mentioned. It attacks the nostrils of the sheep, and the distress thus occasioned is so great that the poor animals, in order to avoid the flies, will often bury their nostrils in the dusty hollows of cart-ruts, further protecting their heads with the fore feet. The members of any flock thus attacked will also collect together in groups, and jostle against one another with their heads downwards, so as to avoid the flies as much as possible. When struck by the fly they stamp the ground violently, and exhibit other signs of distress, sometimes amounting to agony. According to Mr. Riley, as quoted by Verrill, the young larva is itself deposited at the margin of the sheep's nostrils, having quitted the egg whilst yet within the oviduct of the parent insect. Be this as it may, the young larvae having once gained access to the nasal passages, have no difficulty in retaining their hold, at the same time that they cause fresh distress to the unhappy bearer. Within the cranial sinuses they firmly anchor themselves by means of a pair of cephalic hooks, and in this situation they remain until they have perfected this stage of their larval development. Considering the situation of these creatures, there need be no astonishment at the fact that their presence sometimes gives rise to terrible sufferings on the part of the sheep; the afflicted animals occasionally perishing under the inflammatory action thus set up. Stock-owners and farmers term this disease grub in the head, and it is often asserted by them that the grubs gain access to the substance of the brain itself. They are perfectly sure they have seen maggots in the brain, and no arguments of the veterinarian, derived from a study of the osteology of the
sheep's head, will serve to convince them that they are in error. Without dwelling upon this point, we have further to observe that the perfected bots usually pass from the nostrils to the ground by the same way that they entered, and thence-forward having penetrated the soil, they accomplish their subsequent metamorphosis in a manner very similar to that of their congeners. The pupal state is acquired in about two days, but they remain concealed in the soil for a period of six or eight weeks. At the expiration of this period the lid of the cocoon is raised, and the insect prisoner makes its escape in the usual manner.

In perusing the above remarks, it will be noticed that, if Mr. Riley's statements are to be accepted as correct, the gadfly of the sheep reproduces viviparously. This is a point of considerable interest, since, so far as we are aware, all the other gadflies bring forth their young in the egg condition. According to Verrill, who quotes from the First Annual Report on the Native Insects of Missouri (given in the Connecticut publication already cited) for 1868, Mr. Riley states that Mr. Cockrill had removed upwards of three hundred living larvae from the body of a single gadfly. Soon after the flies have effected their escape from the cocoon, they set about operations for the continuance of the species; and as they are neither furnished with a mouth nor other means of taking in nourishment, it is obvious that the pleasures they enjoy during the winged state must be exceedingly short-lived.

TRACHEARIA.

As with the dipterous insects, so with the members of this large order or division of arachnidae. Whilst many species are externally parasitic, only a very small number can in any true sense be called entozoa. One species, however, of the present group is not only internally parasitic in the larval state but also in the full-grown or sexually mature condition; consequently it has even more right to be regarded as an entozoa than any of the gadflies. The parasite in question is the Pseudotoma tenioides. In the adult state, this worm occupies the nasal and frontal sinuses of the dog, sheep, and horse; and in one of its larval stages it is found either encysted or free in the viscera.
of various animals, especially ruminants, as well as in man himself. The larva, which is commonly described as the *Pentastoma denticulatum*, usually measures about one-fifth of an inch in length; but the adult males are three-quarters of an inch long, whilst the females occasionally measure as much as four inches from head to tail.

The history of the development of these curious parasites is somewhat remarkable and of great practical interest. The female discharges her eggs whilst within the nose of the dog. From the nasal passages the eggs are constantly discharged by sneezing and otherwise. They are thus scattered by the canine host in all directions, and by the drying of the slime they adhere very readily to vegetable and other matter. Afterwards, on being transferred to the stomach of ruminating and other animals, their embryonic contents are set free by the dissolution of the shells. The embryos, which are furnished with two pairs of claws, then bore their way into the liver and other viscera. They next become encysted and change their skins. After a time, the larvae are set free, but their wanderings are ordinarily of no avail, unless portions of the infested animal are brought in contact with the nose of the ultimate bearer. In the case of the dog, this commonly happens when the animal is engaged in devouring portions of fresh viscera carelessly flung to it. The larvae are thus brought in contact with the dog's nose, and then, by means of the hooks and spines with which they are armed, the young pentastomes readily adhere to the nose, and in a short while crawl up the nasal passages, where they rapidly acquire sexual maturity. It is not so clear how they make their way into the nasal cavities of the sheep and horse; but in all probability some larvae escape from the bodies of their intermediary bearers into open pastures, and thence into the nasal organs whilst these animals are grazing. Dogs that frequent knackerries and slaughter-houses are particularly liable to become infested by the adult parasite. Such larvae as do not succeed in escaping their cysts perish by calcareous degeneration.

To the veterinarian these facts of development are chiefly important as explaining how dogs contract the parasite; and although instances of suffering from these entozoa may not be common, there is every reason to believe that examples of the kind are not unfrequently overlooked. It is certain that dogs
sometimes suffer severely from worms in the nose, the parasites giving rise to nasal catarrh, accompanied by foetid discharge. There is one remarkable case on record, in which death was occasioned by pentastomes. This is the instance already mentioned as having been made public by Professor Dick in the pages of the *Veterinarian* for 1840. The communication is most interesting and instructive. Three of these parasites having wandered into the fauces and trachea of the dog, its death resulted, partly from spasm of the laryngeal muscles and partly from inflammation of the left lung, accompanied by excessive bronchial secretion. In short, the animal was suffocated.

**Ascarides and Lumbrici.**

The *Ascaris megaloecephala* of the horse and *Ascaris vulva* of the hog are considered by some helminthologists to be identical with the *Ascaris lumbricoides* of man. Dr. Cobbold and others take exception to this conclusion, and consider that they are distinct species.

These worms, best known amongst veterinarians as the *lumbrici* resemble the common earth-worm in size and shape; the males are shorter than the females, which sometimes measure from twelve to sixteen inches in length. They are found in the small intestines; sometimes, but rarely, in the stomach. If few in number, they occasion no inconvenience to the bearer; but if numerous, and particularly if they infest the stomach, they, like bots, may cause colic, indigestion, unthriftiness, and emaciation. After the death of the bearer, several of them are generally found matted together, and coiled up in the form of a ball, leading one to conclude that they have thus caused an obstruction during life. Numerous observations in the dissecting room enable me to state that they assume this form after the death of the host; that they congregate together, interlace one with the other, very shortly after the animal which they infest has died.

In the dog, round-worms—*Ascaris marina*—especially if they enter the stomach, cause convulsive fits, vomiting, and sometimes death.

*Oxyurus curvula,* or better known to veterinarians as *ascarida.*
are small white worms—needle or whip worms—which commonly infest the rectum, and very often the colon, being very abundant in the flexures of that intestine. They escape by the anus, and cause irritation, manifested by the horse rubbing its tail against any hard substance, such as the walls of its stable, or whisking it about in an irritable manner. If the anus and perineum be examined, small masses of a yellowish-white looking substance will be found adhering to the skin; these are the eggs of the worms discharged from the body.

_Treatment._—It is a difficult matter to destroy these parasites. Sometimes an aloetic cathartic will cause the expulsion of numerous _lumbrici_ from the horse, but the remedy is uncertain. Oil of turpentine stands in high repute, and doubtless is more anthelmintic than any other in the horse, but it cannot always be depended upon. Aconite, in some instances, will cause the expulsion of the parasites, as is seen when it is employed in the treatment of inflammatory diseases. When associated with emaciation and debility, the salts of iron prove of much service; they not only have the effect of destroying the worms, but, by causing an improvement in the general health of the animal which they infest, render it an unfit habitat for the parasites, for it is a well-known fact that when the condition of the animal's body is weakly, it is more liable to be infested by parasites of various kinds.

In the dog, emetics will sometimes cause the expulsion of the _Ascaris marginata_ when in the stomach; if these fail, santonine, in from three to five or eight grain doses, according to the size of the animal, or the etherial extract of the male shield fern, is to be administered every second or third day, taking care to watch their action upon the patient, as santonine will sometimes cause straining and other signs of irritation.

The _oxyuris_ may sometimes be destroyed in great numbers by enemata, consisting of decoctions of quassia, gentian, or even wormwood. These enemata are to be frequently repeated, and their action may be aided by purgatives. The introduction of a small piece of mercurial ointment into the rectum is a very common practice in some parts of the country, and it seems to answer very well, not only preventing the migration of the parasites, but actually destroying them,
There are many other remedies recommended by helminthologists, many of which are very serviceable, whilst others are only calculated to do harm. I need only refer to the insane practice of administering ground glass and other mechanical irritants, in order to warn the reader against what is absurd.

Other nematode worms infesting the lower animals, and found in the blood-vessels and eyes, are briefly referred to in my work on Veterinary Surgery, to which the reader is referred.
CHAPTER LXXIV.
PARASITIC DISEASES—continued.

DISEASES CAUSED BY NEMATODA OR ROUND-WORMS.

PARASITIC DISEASE OF THE LUNGS.

In the calf and lamb, bronchial irritation, arising from the presence of nematode parasites, termed strongyles, is of frequent occurrence, and is variously termed The Husk, Hoose, Phthisis pulmonalis terminalis, and Parasitic bronchitis.

In the lamb, the parasite, termed Strongylus filaria, is from one to two and a half inches long; the female is white, larger than the male, which is of a yellowish-white colour, and its body is of uniform size, but tapered at both ends. The head is short, stumpy, rather angular, but not tuberculated as in other strongyles. Extending from the mouth is a short oesophagus, entering the stomach, from which a straight intestine is continued nearly to the extreme end of the tail. The tail of the female is pointed; the oviducts, filled with eggs and live young, extend into the vulva, which is situated close to the anus.

The anatomical situation of the parasites in the lungs of lambs and sheep is not always the same. In lambs they are found not only in the bronchial tubes, but also in the lung-substance, whilst in sheep they are generally encysted in the parenchyma of the lungs, giving them the appearance of being filled with small tubercular deposits; indeed, the disease was for a long time looked upon as a true tubercular affection. I am of opinion that within the last few years the disease is more commonly met with, and during the winter and spring of 1873-1874 I had more opportunities of witnessing it than in any former years.

The lungs of sheep which have been the hosts of these parasites are thickly covered with numerous small nodules, varying
in size from a pin-head to a hemp-seed, or even larger, and resembling small vesicles or blisters. Some are filled with a clear fluid; others contain a soft material, consisting of granular matter; whilst others are hard and gritty,—and all minute worms coiled upon themselves.

The varying degrees of hardness and consistence of the nodules mark their age; the vesicle seems to be their earliest development; the soft, solid condition a more mature condition; and the gritty state shows that the wall has undergone calcification and that the worm has been lodged in the lung tissue for considerable period.

The presence of these parasites in the lung does not always cause irritation or inconvenience to the host. The lungs of sheep killed in the primest condition are found loaded with them. Occasionally, however, they induce debility, anæmia, and cause death, more particularly in lambing ewes, at or about the period of parturition. Many ewes died from this cause during the lambing season 1874.

In lambs, however, the parasites find their way through the softer lung structure into the bronchial tubes, and there give rise to irritation, and to the symptoms of the "lamb disease".

It is supposed that the parasite is developed in the lamb only and that those found encysted in the lungs of sheep have been long imprisoned as it were by a boundary line of plastic inflammation, which finally becomes calcified, and offers an impassable barrier to the movement of the strongyle.

Whilst admitting the greater frequency of the affection in lambs than in sheep of a more mature age, I cannot subscribe to the above conclusion, as the results of examinations of the lungs of four or even five year old ewes have shown conclusively that many cysts are not in a state of calcification—condition that they certainly would be in, if the parasitic invasion had occurred when they were lambs. The manner by which parasites gain access to the lungs has been a matter of controversy. Dr. Edward Crisp, in an essay on this disease, for which a prize of £30 was awarded by the Bath and West of England Agricultural Society, accounts for their presence in the lungs by a direct passage into the trachea from the mouth, where they have been forced from the stomach during the act of rumination. Mr. Dickinson, M.R.C.V.S., Boston, Lincolnshire, Professor Armstrong
as well as Professor Gamgee, oppose this view. Mr. Dickinson says—"The idea entertained of a direct passage of these to the lungs appears to me paradoxical and in no wise probable. Their migration, I am inclined to believe, is a work of time; and hence, as I have frequently observed, the parasites abound in the alimentary canal in large numbers, give rise to aggravated symptoms which terminate fatally when no worms or their eggs are to be detected by the naked eye, at least in the lungs or bronchi." Professor Armatage informs me he has also observed this in many instances. Mr. Armatage says—"The presence of Strongyloides filaria in the lungs of lambs and sheep, I think, cannot be explained by any theory which describes—no matter with what minute exactness and elaborate detail—the unnatural and, I might add, almost impossible mode of their passing direct through the windpipe to these organs. We all know, as possessing some slight knowledge of physiology, how a hair, a bread-crumble, drop of water, &c., will irritate the glottis or entrance to the windpipe, and give rise to the most painful and convulsive coughing. These are, however, objects of an inanimate character, and irritate by mere presence. How much greater, then, would be the effects of a live worm or worms insinuating themselves on the delicate structures, and especially when the natural barbs or hooklets, as described by Professor Simonds, are put in operation. The supposition, I think, suffers much under the great probability that violent coughing taking place on the entrance of a worm or worms would entirely expel them. If they are expectorated in large numbers from the recesses of the bronchial tubes, they will most assuredly be compelled to evacuate much more rapidly at their entrance to the windpipe."
The same gentleman further says—"We must not overlook the important fact that young lambs are principally affected. In them the tissues are more easily pierced, and their passage from the lung tissue to the bronchial tube readily effected. In older animals they remain enveloped within a matrix of cartilaginous substance and metamorphosed lung tissue, in order, as it were, to guard against their effects. If their passage to the lungs were always more direct, the opposite would be the case, and our old animals would die as rapidly as the young ones." Professor Gamgee says—"The migration from the mouth or alimentary canal to the lungs certainly requires a more complete explanation than has hitherto been given."
There is no doubt in my mind but that the ova and young parasites taken up with the food, in the first place gain access to the alimentary canal into the circulation, and are conveyed to the lung-substance, where they are deposited, the parasites then mature piercing the tissues and entering the bronchial tubes, and there cause the irritation symptomatic of the disease, whilst those remaining encysted in the lung cause little or no inconvenience (see fig. 34). It is very true that in many instances the parasites are found fully matured in the digestive canal, and doubtless the conclusions of Dr. Crisp are due to this fact. We can, however, easily understand that the heat and moisture of the stomach are quite sufficient to cause the ova to hatch and some of the embryos to mature in the intestinal canal, whilst others embryos pierce the intestinal wall and are taken into the circulation, and mature only when they have been deposited in their proper habitat; and a few may become fully developed in the blood. I have on two occasions seen the parasite in the cavities of the heart and in the blood-vessels; and I think this fact conclusively points out the correctness of this view of their migration.

The tenacity of life in the young strongyle is very great: Ercolani found that they showed signs of life on being moistened after drying for thirty days, and at other times after having been immersed in spirits of wine at 30°, or in a solution of nitric and corrosive sublimate.—(GAMgee.)

The number of embryo worms in the lungs of one sheep is very great; if to these we add those hatched in the digestive canal, we can easily understand, when these are gradually discharged from the infected animal, how a pasture may become infected with parasites and ova to such an extent as to infect a whole flock.

Dr. Crisp says the disease is due to over-stocking, and especially to the feeding of lambs off a second crop of clover, after the first crop has been consumed by sheep. The mere feeding of lambs with the second crop of clover, after the first has been consumed by sheep, would not of itself be sufficient to cause an outbreak of the lamb disease; but when we consider that a very large number of sheep are infested with the parasites, from which they seem to suffer no harm, we can easily understand how, by the expulsion of some of these from the infected pasture may become fouled by the parasites and their ova.
PARASITIC DISEASES OF THE LUNGS.

I can offer no explanation as to the source from whence the *Strongylus falaric* is originally derived, and can only say with Dr. Cobbald, that, "with the exception of the *Trichina spiralis*, I am not aware that we have a thorough knowledge of the entire life history of any of the nematode species which infest the human body; nor, indeed, can I call to mind any round-worm infesting the lower animals, whose life phases, migrations, and peculiarities of structure during development are satisfactorily known."

We know, however, that the disease prevails particularly in low, damp situations; on lands subjected to be flooded by the overflowing of rivers, or after heavy rains occurring during early autumn or the latter part of summer.

*Symptoms.*—These are subject to some modification, depending upon the seat of the parasites. In the majority of cases, they are found in the lungs, in others in the lungs and digestive organs, whilst in others again they are found in the stomach and bowels only—the lungs being entirely free from them. When in the intestinal canal the symptoms are those of dysentery, with fetid stools; there is much tenesmus or straining, and occasionally clots of fetid blood are discharged *per rectum*. The lodgment of the parasites in the pulmonary tissue and bronchial tubes cause, in the lamb, irritation and inflammation, indicated by cough, rubbing the nose on the ground, and accelerated respiratory movements, whilst in the more mature animal—the sheep—the presence of the parasite may induce no diagnostic signs, even in those which succumb, and it is only after death that the cause of the emaciation and anemia, which may have been present during life, is discovered. In many cases the abdominal symptoms are accompanied by depraved appetite, intense thirst, and even colicky pains.

When the parasites are in both the lungs and bowels, there will be a combination of pulmonary and enteric irritation, and very rapid sinking. If the expectoration and alvine discharges be carefully examined some of the parasites are sometimes discoverable.

*Treatment.*—This naturally divides itself into preventive and curative.

To prevent the disease lambs require to be fed on fresh pastures; second and third year crops are to be specially avoided, if they have been previously grazed by sheep. If the
seasons are damp, the flocks are to be pastured on the hillside, or on dry pastures; and if the grass be scarce, it is to be supplemented by artificial food.

To cure the disease, or rather to destroy its cause—the parasites—inhalations of chlorine gas have been recommended. If using this agent great care must be taken that it be sufficiently diluted with air, so as not to destroy the patient as well as the parasite, for I have heard of individuals who have applied it sufficiently strong to destroy all their patients. It is therefore better to compel the animals to inhale it from the chloride of lime, to which sulphuric acid has been added, than to manufacture it in the ordinary way, namely, by the admixture of common salt, peroxide of manganese, and sulphuric acid. Should the animals be thought too weakly to stand the chlorine gas sulphurous acid may be substituted, and this is so cheap and so much safer than the chlorine that I much prefer it. It is made by burning sulphur, which, combining with oxygen during the combustion, gives off fumes of sulphurous acid. Of course it will be understood that when animals are made to inhale either of these gases, they are to be confined in some building. Where the parasites are in the intestines, several doses of turpentine or to be administered. The debility from which the animals suffer is best combated by stimulating food, as the cakes, to which a sulphate of iron—from ten to twenty grains for each lamb—has been added. Rock salt should also be allowed the animals to lick, or a small quantity of common salt added to the food.

*Hoose in Calves.*—This disease very closely resembles that in lambs; and is caused by a parasite termed the *Strongylus microstoma* (Mehlis), which gains access to the pulmonary tissue and bronchial tubes through the circulation, the ova being absorbed from the digestive canal. This parasite is very tenacious of life, and will be seen to be quite lively in the pulmonary organs several days after the death of its host. It is one of the armed strongylids, has a filiform body, and a mouth with three papillae.

This disease prevails in low-lying districts, on land near rivers, more especially after heavy floods, and is mostly seen in the months of August, September, and even October, in calves under one year old, and very rarely in those rising two years old.

* I found this parasite in the lungs of several full-grown American ewes during the spring of 1879.
Sometimes the worms are very numerous in the trachea and bronchial tubes, and not unfrequently one finds them congregated together, after the animal's death, in a perfect ball, effectually obstructing the windpipe.

I have watched the movements of the embryos of this parasite under the microscope, and have seen them burst through the walls in which they have been enclosed, and make their escape.

This parasite has also been found in the air passages of the horse and ass. A similar affection has been observed in the pig, the parasite being called *Strongylus suis*. In poultry the disease termed the "gapes" is caused by a parasite called *Sclerocestoma syngamus*.

The symptoms in the Calf.—The seat of the irritation is indicated by a bronchial cough, "husk or hoose," loss of flesh, a varying degree of constitutional disturbance, and death by suffocation if the sufferer be not relieved. If any mucus be coughed up and examined the parasites may be discovered. Bronchial irritation occurring in calves during summer or autumn should always be looked upon with suspicion, and its source thoroughly inquired into. If any calves be already dead, a careful post mortem examination ought to be made, in order that the pathological condition of the lungs should be determined. If none are dead, the mucus from the nose should be examined, when in all probability some of the parasites will be discovered.

Treatment.—The calves are to be warmly hosed if the nights be cold; the affected animals are upon all occasions to be removed from the healthy; not that the disease is contagious in itself, but that the parasites or their ova, discharged from the sick, are apt to gain access into the bodies of the healthy, and for the same reason the healthy should be removed to fresh pasture and to dry situations, as the fields upon which the disease has prevailed will, for a time at least, be tainted by the parasites and ova.

Inhalations of chlorine or sulphurous acid are recommended. If this be carefully done, the sufferers may be kept surrounded by either of these for about fifteen minutes each day, until the disease disappears; two or three inhalations are generally sufficient. If inhalation be objected to, turpentine may be administered in gruel daily, or, what has succeeded well with me, from ten to twenty minim doses of Scheele's hydrocyanic acid, with
carbonate of soda, and some bitter stomachic, as gentian or chamomile, twice per day. The acid seems not only to have the effect of destroying the parasites, but also of allaying the bronchial irritation in a very short space of time.

The "gapes" in fowls, due to a parasite in the air passages the Sclerostoma syngamus, and indicated by gaping, gasping for breath, sneezing, and frequent attempts at swallowing, is treated as recommended by Professor Cobbold and others.

"First. When the worm has taken up its abode in the trachea of fowls and other domesticated birds, the simplest plan consists, as Dr. Wissenthal long ago pointed out, in stripping the feather from the tube to near the narrow end of the shaft, leaving only a few uninjured webs at the tip. The bird being secured, the webbed extremity of the feather is introduced into the windpipe. It is then twisted round a few times and withdrawn, when it will usually happen that several of the worms are found attached. In some instances this plan entirely succeeds. But it is not altogether satisfactory, as it occasionally fails to dislodge all the occupants.

"Secondly. The above method is rendered more effectual when the feather is previously steeped in some medicated salvia which will destroy the worms. Mr. Bartlett, superintendent of the Zoological Society's Gardens, employs for this purpose salt or a weak infusion of tobacco; and he informs me that the simple application of turpentine to the throat externally is sufficient to kill the worms. To this plan, however, there is the objection that, unless much care be taken, the bird itself may be injuriously affected by the drugs employed.

"Thirdly. The mode of treatment recommended by Mr. Montagu appears worthy of mention, as it proved successful in his hands, although the infested birds were old partridges. One of his birds had died from suffocation; but he tells us that a change of food and change of place, together with the infusion of rue and garlic instead of plain water to drink, and chiefly hemp-seed, independent of the green vegetables which the grass plot of the menagerie afforded, recovered the others in a very short time."

"Fourthly. The plan I have here adopted, by way of experiment, of opening the trachea and removing the worms at once. This method is evidently only necessary when the disease has
PARASITIC DISEASE OF THE LUNGS.

advanced so far that immediate suffocation becomes inevitable; or it may be resorted to when other methods have failed. In the most far-gone cases, instant relief will follow this operation, since the trachea may with certainty be cleared of all obstructions.

"Lastly. The most essential thing to be observed, in view of putting a check upon the future prevalence of the disease, is the total destruction of the parasites after their removal.

Intra-tracheal injections for hooze in caeca.—Recent experiments have demonstrated that drugs may be injected into the trachea with impunity, and that hooze may be most advantageously treated with remedies administered by this method. Turpentine, prussic acid, carbolic acid, and creosote may be used in this way. The turpentine and creosote should be mixed with either oil, or an emulsion of oil, water, and alkali, as in the following:—B: Ol. tereb. 3ij; ol. olivæ, 3j; potassæ carb., gr. xx; sqœæ, 3j. Inject this quantity daily for three days. The injections are given with the hypodermic syringe. Make a small incision through the skin at the site for tracheotomy, pass the needle of the syringe into the trachea between two of the rings, and inject.

Corrosive sublimate, one of the most powerful parasiticides known, might be tried in the form of intra-tracheal injection—gr. ¼ to gr. ½ in 3ij or 3iv. of water.

PARASITIC GASTRIC CATARRH.—(Gastrorrhea Parasitica.)

A disease of the fourth stomach of the sheep, caused by the presence of the nematode worm called the Strongylus contortus.

The following is a short history of an outbreak of disease in sheep induced by this parasite, and to which my attention was called by Mr. Connachie, V.S., Selkirk, in March of this year, 1884.

It appears that the owner of the sheep in question had placed his lambs, after weaning time, upon a very luxuriant pasture, but from the nature of the autumn of 1883, which was very wet, the grass became rank and the soil damp, notwithstanding it had been previously well drained both on the surface and underground.

After thriving well for some time, they began to lose flesh very rapidly, and give other indications of disease; they were then removed to another pasture of good clean grass, and shortly afterwards placed on turnips, oads, and Indian corn. This change seemed to have the desired effect, as they commenced to thrive and lay on flesh; but in the month of February 1884, when nearly fat and fit for the butcher, the now hoggets suddenly
presented signs of disease. Their appetite at first became voracious; they then ceased eating their food altogether, but would devour earth or any rotten or decaying vegetable matter. For this time other and more serious symptoms soon developed themselves, such as great restlessness, lying down and suddenly rising again, pawing with the feet and showing signs of abdominal pain. The bowels now became very irritable, and from being constipated became very loose, the evacuations being like muddy water. At this stage a most unnatural desire for water was evinced, the sheep roaming about in search of it and when driven away from it, immediately returning to it. Along with this insatiable thirst, there was also an almost constant desire to urinate, the urine passed being as clear as water.

The cough now became hacking, but intermittent, each fit of coughing continuing until the animal succeeded in ejecting a quantity of frothy mucus, which relieved it for a time only. The fits soon returned and became more frequent; during intervals a flow of watery saliva continued to dribble from the mouth, accompanied by a constant grinding of the teeth, and continual twitching of the nostrils and upper lips.

During the development of the above symptoms the hair had most rapidly lost flesh, the adipose and muscular tissues being rapidly atrophied; the abdomen becoming greatly distended, causing the animal to present a most miserable appearance. All the above symptoms increased gradually and steadily until death closed the scene.

After trying various remedies without success, Mr. Connachie advised the owner, Mr. Elliot, Hollybush, Galashiels, to call me into consultation.

Before seeing the sheep in consultation with Mr. Connachie, one carcase was sent to the College for examination.

In the lungs of this sheep the *Strongylus filaria* was found, but not in great numbers; the parasites were also found in the blood vessels of the lungs, causing embolism; and in the fourth stomach the *Strongylus contortus* was found in great numbers. After the examination I visited Hollybush, and saw several sheep in an advanced stage of the disease, and, in addition to the above symptoms, furnished by Mr. Connachie, found that the majority presented aggravated symptoms of oedema of the head, affecting the nostrils and interfering with the breathing, and involving the intermandibular space and inferior cervical region as low down as the breast.
Strongylus Filaris, embryonic stages, in aircell of Lunga

Strongylus Contortus.—Bursa of Male
(× 50.)

Strongylus Contortus.—Genital papillae of Female
(× 50.)
On making a post mortem examination of one sheep killed for the purpose it was found that the *Strongylus filaria* was absent, but that the true stomach (abomasum) contained a quantity of a dirty looking fluid, in which the *Strongylus contortus* could be seen wriggling in great numbers.

The parasites were so small as to be seen in the fluid with difficulty by the naked eye, but by gently moving the walls of the viscus, the whole fluid would seem to be one seething, fermenting mass of wriggling, moving worms; whilst the body of the animal was very anaemic, the muscular tissue greatly wasted and very pallid, the fat fairly abundant, but presenting the very white appearance seen in liver-rot and other anaemic diseases.

The *Strongylus contortus* has been studied in Germany by Gerlach particularly, and the following is a brief résumé of his conclusions.

The *Strongylus contortus* occurs in the fourth stomach of the sheep and goat, and when present in large numbers causes disease (*Magenwirrmereuche*). At the same time, as was first noticed by Gerlach, the *Strongylus filaria* is usually present in the lungs. In the summer the *Strongylus filaria* is most abundant; in autumn the *Strongylus filaria* and *Strongylus contortus* are almost equally numerous; while in winter the *Strongylus contortus* prevails, and the *Strongylus filaria* has almost disappeared. Hence the stomach disease caused by *Strongylus contortus* breaks out in winter and spring in those lambs which have survived the lung disease of summer and autumn.

These facts agree with what was observed at Hollybush, namely,—1st. The appearance of disease early in the autumn amongst the sheep. This would be due to the lung disease caused by *Strongylus filaria*. 2d. The recovery of many of the sheep affected when the diet was changed, i.e., when removed to a clean pasture; and 3d. The appearance of the disease later on in the season, in February 1884, and resulting from the *Strongylus contortus*, confirmed by the post mortem examinations, in one of which only a few *Strongylus filariae* were found.

From this connection between these worms, Gerlach was led to make the following experiments:—Eggs of *Strongylus filaria* were given to healthy goats and lambs, and, four months after the feeding, *Strongylus contortus* was found to be present. From these experiments Gerlach concluded that *Strongylus contortus*
could develop from the eggs of the Strongylus filaria. In opinions differ upon this point.

The name Strongylus contortus occurs first in the writings of Rudolphi, and the species was described from specimens found in the month of November in the fourth stomach of a bovine. Fabricius also found them in the intestine.

Description.—The body is cylindrical, red or white, and taper very gradually towards the anterior extremity, where is the orifice (fig. 35), which is unprovided with papillae or other appendages, and leads into the muscular pharynx, rather more than 1 mm. in length, in a worm 25 mm. long.

The male is smaller than the female, and is from 10 to 16 mm. in length, and 0.2 mm. in diameter.

The terminal bursa consists of two elongated ovoid lobes, one of which is supported by five ribs, and attached to the left side is a smaller one, supported by two ribs. There are two spines, about 0.5 mm. in length, each one tapering to a fine point, which is slightly curved outwards. Under a high power each point is seen to be tipped by a small knob. (Fig. 36.)

The female is from 18 to 30 mm. in length, and 0.3 mm. in diameter. The body tapers very suddenly to an extremely fine point, and about 3 mm. in front of this is the genital opening, furnished with two papillae, of which the left is much larger than the right (fig. 37). The uterus is convoluted, hence the name Contortus.

Symptoms.—The symptoms of the stomach disease caused by the Strongylus contortus are, according to Gerlach, not sufficiently marked to allow of a certain diagnosis. The animals are languid and dejected, and tend to become lean and anaemic; the excrement is thin and brown, mixed with slime, or at times with blood. At last cachexia occurs, and death ensues from starvation (Erschöpfung). On post mortem examination the fourth stomach is found with hundreds of the Strongylus contortus, covering its surface.

Treatment.—Good food is recommended, e.g., roasted malt seeds, lupine hay or lupine seeds, and the following medicines:

Chabert’s oil, . . . . 1 part.
Oil of turpentine, . . . 3 parts.

The dose being one teaspoonful per day.

Kamala has been recommended, and the picrate of podophyll is highly spoken of by Zurn.
Rabe used picrate of potash in the small dose of 0.12 grms., or about 2 grains per day for three days, and was successful in his treatment. The picrate of potash was given in thick linseed mucilage.

The doses of picrate of potash as given by Zurn are—

For a lamb 0.30 grms. or about 5 grains.
For a sheep 1.25 "  or about 20 grains.

Divided into two doses per day.

It is now believed that the ova of these parasites, passed from the body of their host, retain their vitality in damp places only, and that where nice bites of green grass, such as that growing on the sides of open drains and damp spots in pastures otherwise dry, are sources of danger, the parasitic ova becoming infested with such grasses. The prevention of the disease by the destruction of the worms should be attempted by first digging up, where possible, all such green grasses, and inverting the sods. 2d. By a liberal application of salt to the land, and, where possible, an allowance of it to the sheep.

During wet seasons the above precautions are impossible, and all that can be done is to remove to the driest pastures, give corn where possible, and an allowance of common salt in the food.

In March 1873, an Iceland pony rising two years old, which had been under my care for some weeks, died from what appeared to be an exhausting disease, and, as stated in a letter to Dr. Cobbold, there were no very marked signs of the presence of parasites during life. The appetite was good; there was no cough; and we were led to suppose that there were worms by the absence of disease more than anything else. There was gradual emaciation, but no diarrhoea, and at no time were the faeces faecal. As bearing upon the discovery of this parasite, I may state that Dr. Knox, who wrote in the Edinburgh Medical and Surgical Journal for 1836, says—"On two occasions my friend Mr. Dick found parts of the large intestines of a horse presenting the following appearance: the gut being simply laid open so as to exhibit the mucous membrane, a number of dark spots are observed, evidently exterior to the inner membrane." And, further on, speaking of the worms, he adds: "they have no cyst, and vary from the tenth of an inch to a length
of at least seven-tenths. They have a digestive tube divided into numerous compartments or sacculated; a mouth unarmed."

Professor Dick's own statements, as communicated by Dr. Knox, are particularly interesting. He says—"I have found these worms in several horses, and at different stages of their growth, from the size of a pin-point to that of an inch and a half in length, and in two instances in the blood-vessels.

"They seem almost always to produce a bad form of diarrhea, and seem to depend on the food or situation in which the animal has been previously kept. The horses I have found affected with these have always been running out previous to their becoming ill."

During the spring of 1874 I had again the opportunity of studying the disease caused by this parasite, or rather parasites, for I am of opinion that there were at least two kinds present in the subjects examined by me, some being embedded in the intestinal walls and others in the intestinal canal, the latter being a reddish-looking worm, very similar to a small earthworm, from two to three inches in length. Those embedded in the intestinal walls, as well as the appearance of the intestines, are delineated in the following woodcuta.

![Fig. 38.](image1)

![Fig. 39.](image2)

*Microscopic appearance of Stomylis intermedius embedded in mucous membrane of Iceland pony, described in the text. These worms were of a bright red colour. (About 100 diam.)*
Fig. 48.—Appearance of mucous membrane of colon of Iceland pony, natural size.

I may state that all the ponies affected were rising two years old, and that several had died before my opinion was sought. They had been imported from Iceland during the summer and autumn of 1873, and thriven tolerably well until late in the winter. They were at pasture during the whole winter and spring, being allowed hay in addition to what they could graze. There were many older animals amongst them, the lot being a large one, all of which were quite free from the parasites.

The question naturally arises, Are these parasites peculiar to Iceland? and at the first glance, my own experience would compel me to answer in the affirmative; but the observations of others at once point to the conclusion that other than Icelandic ponies are subject to the invasion, and Dr. Cobbold has arranged the following list of those who have written upon the subject:

"Dick.—'Worms at different stages of growth;' in MS. to Dr. Knox, 1836.

"Knox.—'Animals similar to Trichina;' in Edin. Med. and Surg. Journ. (loc. cit.)

"Diesing.—'Nematoideas equi caballi;' Syst. Helm., vol. ii. 1851.

"Lüttler.—'Extremely small ascarides;' in a letter to Mr Varnell; The Veterinarian, 1864, p. 202.

"Varnell.—Entozoa in various stages of growth;' The Veterinarian, n.d. supra, p. 265.

"Williams.—'Entozoa from the intestinal walls;' in MS. to the author, March 13, 1873.

"Cobbold.—Trichonema arcuata, a new species of nematode (with description as below).
PARASITIC DISEASES.

"Body spindle-shaped, more narrowed posteriorly than in test: head truncate, with circular mouth, cup-shaped buccal cavity, and muscular cesophagus; tail of the male drawn out to a long fine point that of the female being abruptly pointed; reproductive papillae of the female situated at the lower part of the upper third of the body.

"Size.—Males, \( \frac{1}{10} \) to \( \frac{1}{9} \) of an inch in length, by \( \frac{1}{10} \) to \( \frac{1}{7} \) \( \frac{1}{8} \) breadth; the females averaging \( \frac{1}{8} \) of an inch in length by \( \frac{1}{8} \) \( \frac{1}{8} \) breadth."

The opinion that this was a new species of nematode was found to be a mistake, as even Cobbold had referred to it in 1873, and Küchenmeister in 1857.

Symptoms.—In the pony under observation in 1873 diarrhea was absent throughout. Mr. Justus Littler, who was then a student with me, was able, however, to see some points of resemblance in the symptoms to those described by his father in the letter to Mr. Varnell, above mentioned. In the lot observed in 1874, diarrhoea of a fetid character, along with a more or less rapid emaciation, was present in all the cases, and I conclude that, in conjunction with the ages of the affected animal diarrhoea and emaciation may be considered as diagnostic symptoms. Four of the 1874 lot were so reduced as to be unable to stand; they were recumbent, very quiet, with pallid mucous membranes; the appetite was, however, good. The question again arises, Was the diarrhoea due to the presence of the large worms in the intestinal canal? and one is led to conclude that from the fact that none were discovered in the first case, this symptom arose from this cause, and that so long as the parasites were passive in the intestinal walls they did not cause superabundance of the bowels, but as they became matured and burst through the tissue surrounding them, they irritated the intestines and caused purgation. In addition to the dark spots on the mucous membrane of the colon, delineated in the woodcut, the intestinal glands were, in all the cases examined, more or less enlarged, many of them containing pus and what appeared to be debris of the parasites. In every instance the dark spots, which in reality indicated the seat of the worms, were confined to the colon. An experiment was made with the flesh of the first pony upon some fowls, and, as stated by me in my letter to Dr. Cobbold, two of them died, with the livers and other viscera filled with parasitic ova and embryos.
Mr. Cawthron of Hadlow has found these parasites enveloped in cysts of vegetable débris.

Treatment.—In the cases treated in 1874 we were successful in every instance by administering two-drachm doses of the oil of turpentine night and morning, along with eggs and milk well beaten up. The eggs and milk were administered, not only for the reason that they form a good vehicle for turpentine, but to afford nourishment and support to the debilitated animals.

This is a very interesting subject, requiring further investigation, and it may turn out that the larger worms are a more mature form of the smaller specimens, or that they are a distinct form altogether.

TRICHINOSIS.

The Trichina spiralis is a minute round-worm, measuring about \( \frac{1}{8} \) of an inch in length, originally found in the muscular tissue of pigs, eels, cats, dogs, badgers, hedgehogs, pigeons, poultry, moles, crows, vultures, &c., and transmissible by ingestion of trichinosed flesh to other animals, and to man; but, according to some observers, carnivorous birds are exempt from the invasion of the parasite. The anterior extremity of the worm is rather pointed, its posterior thick and rounded; has immature sexual organs, and lies coiled up in an oval cyst. The cyst, which measures about \( \frac{1}{8} \) of an inch in length, appears to be no essential part of the worm, but forms around it after it has taken up its location; the walls of the cyst are laminated, transparent, and thick, generally studded externally with calcareous matter.

The trichina cysts occupy the striated muscular tissue, and in some specimens it has been estimated that each cubic inch of the striped muscles of an infected hog may contain from thirteen to thirty-five thousand worms. The cysts appear in the muscles as minute white grains, visible to the naked eye, and with their long diameter corresponding to the direction of the muscular fibres. In a cat experimented upon by Leuckart each ounce of muscle was calculated to contain 325,000 trichinae; and Dr. Cobbold estimates that a man of medium bulk may easily harbour 20,000,000. Dr. Bellfield and Mr. Atwood, at Chicago, fed a rat, weighing two ounces, with infected pork in small quantities every two or three days for six weeks. No impairment in the health of the rat resulted; it was then killed, and
its body was found swarming with living trichinae; the observers estimated there were no less than 100,000 in the carcass. They also found that rats may be fed occasionally with small numbers of trichinae without in any way disturbing their health; and the inference drawn from these experiments has been, that any animal or man may take live trichinae in small numbers occasionally without injury. These observations further believe that many more human beings than have heretofore been supposed are infected with trichinae; indeed, it is probable that a majority of us are carrying these worms in our muscles. Some have felt of this fact, that one of them ate a living trichina on 20th November 1878, and after more than three weeks had elapsed—when the case was reported—the slightest effect had been experienced. These gentlemen discovered that small portions of sulphurous acid dissolved the brine in which hams are pickled will kill the trichina. The percentage of acid was not then fully determined, but the amount is so small that it is no detriment to the meat for commercial purposes.

This worm was first discovered by Professor Owen in 1835 in a piece of a man's muscle, which presented a peculiarly speckled appearance. These specks were found by Professor Owen to consist of minute encysted eutozoa, which he named Trichina spiralis owing to its hair-like and spirally coiled form; but until 1860 it was only known as a pathological curiosity. At that date, however, Zenker of Dresden showed that, however harmless the encysted parasite might be, it graved symptoms, and even death itself, might be caused by its reception into the bowels, during the process of its reproduction which then ensued, and during that of the migration of the young trichinae into the voluntary muscles.

It is not yet determined how long the larval trichinae retain their vitality, but there is no doubt that they may live encysted in the muscular tissue for many years, and retain life after the death and putrefaction of their host. They do, however, persist in situ sooner or later, and usually undergo calcareous change.

When the trichinae capsules are swallowed, they are dissolved by the gastric juice, and the contained parasites are set free; they then rapidly undergo development, and attain sexual maturity.
TRICHINOSIS.

the female acquiring a length of \( \frac{1}{4} \) inch, the male \( \frac{1}{8} \). The males are filled with sperm-corpuses, and the females densely stocked with ova, which are hatched within the uterus, from whence the living embryos escape into the intestinal canal of the host, and at once commence active migration. They first attach themselves to the intestinal mucous membrane, eat through the intestinal walls, and find their way to the small vessels and lymphatics of the bowels, from which they are conveyed by the blood stream to all parts of the body. They have been found during this period in almost every part of the organism; in the intestinal walls; in the abdominal cavity, in the mesentery and mesenteric glands, in the connective tissue, and, in an as yet unencapsuled condition, in the muscular tissue itself.

The immature trichinas taken into the stomach become mature on the second day; on the sixth and following days, up to the end of the second or even third week, the embryos are born, and commence operations, and probably reach their destination in a week or two, and by the end of a month or a little more have come to the conclusion of their labours. Although the trichinas fix their abode in the striped muscular tissue, they are rarely if ever found in that of the heart, but are often specially abundant in the muscles of the larynx.

The experiments of Dr. Bellfield and Mr. Atwood support the conclusions of previous observers, that the manifestations of disease in animals experimentally infected vary according to the number of trichinas introduced; if these have been few in number, no ill consequences have resulted, but when more numerous, the disease has been of an aggravated or even fatal character.

**Symptoms.**—The symptoms of trichinosis in man, as concisely described in Tanner's *Practice of Medicine*, are as follows:—

"The symptoms of trichiniasis vary in degree, being mild or severe according as only a few or many of the worms have been swallowed, as well as in proportion to the number of the progeny and the extent of their migrations. Thus, Dr. Althaus remarks that in the epidemic of Burg, near Magdeburg, a woman who had eaten a quantity of raw pork with bread, fell ill and died; her child, who had sucked a spoon used by the mother, suffered slightly and recovered.—According to the accounts given by most authors, the earliest symptoms are loss of appetite and
general malaise; to which succeed nausea and retching, prostration, diarrhoea, a sense of thorough indisposition, and a pain-stiffness about the neck and arms and legs. This pain is due to the immigration of the young trichines into the muscles; it is accompanied with high fever, and an oedematous swell about the eyelids and face. The pulse is frequent, and the are copious offensive perspirations; but although the temperature of the body is raised it does not reach the same height as typhus and typhoid fever. For some days the stiffness of limbs continues to increase; while all the muscles seem painful and swollen and very sensitive to the touch. The movements of the intercostal muscles in respiration are stertorous with suffering, so that repose is impossible; while there will be troublesome hiccups if the diaphragm be invaded, with hoarseness and loss of voice where the laryngeal muscles get involved. Neuralgia of a very severe description, in the celiac and mesenteric plexuses, has likewise been present in certain cases. When a large quantity of trichinous meat has been eaten, so that the immigration of the trichines into the muscles is great, the patient may lie almost paralyzed in a state of great exhaustion. Facial oedema generally lasts about a week, its disappearance being followed by swelling of the feet and legs, and ultimate of the trunk. There is no effusion, however, into any of the cavities; nor does the urine become albuminous, although it is always lessened in quantity and may be loaded with sugar. About the beginning of the fourth week the patient is in a pitiable condition. The pulse and respirations are very frequent; the tongue is red and dry, the pain is severe, the swelling profuse, the mouth can scarcely be opened, no sleep can be obtained, and there is great anxiety or delirium; death not unfrequently occurring with all the symptoms of profound exhaustion. Such complications as pneumonia, peritonitis, and pleurisy with effusion, are not uncommon. In favourable cases, however, the pain and swelling and diarrhoea abate; the oppression of the chest passes off; sleep is obtained; a desire for nourishing food is evinced; the power of the limbs is regained; and there's only left great anemia, with a falling off of the hair, etc. The parasites have taken up their abode in the muscles, and have fortunately become encysted."

It appears that the symptoms are much more severe in
human being than in the lower animals; and Dr. Cobbold mentions that a pig experimented upon at the London Veterinary College, and in which it was calculated that about sixteen millions of encysted trichinae had been developed, manifested no symptoms of suffering; other pigs, however, showed much general disturbance and suffering, arising from the irritation of the worms in the intestines, and during their passage into the muscular tissues. The irritation of the alimentary canal, which lessens towards the end of the first week after pigs have swallowed trichinae, is denoted by loss of appetite, vomiting, colic, tympanitis, and diarrhoea; dulness, arching of the back whilst standing; and pigs incline to lie down and hide themselves in their litter in this as in many other diseases. These symptoms, with the exception of the diarrhoea, generally disappear in from six to eight days. When the trichinae have been numerous, the membranous passage of a great number of them have, in the experience of Leuckart, induced in some a fatal peritonitis; and in others, a form of enteritis, with ejection of false membrane.

"The muscular symptoms appear towards the termination of the second or during the third week after the ingestion of the trichinosed flesh; while the intestinal phenomena become less marked, and the fever increases in intensity. At this stage the patient is often lying; in walking, it carries its back raised and the limbs stiff, and manifests signs of pain; mastication, opening the mouth, and swallowing are difficult; the voice is harsh, husky, and weak; the respirations laboured and loud; cutaneous edema appears in different places, together with the intense pruritis already alluded to; the conjunctival membrane is most frequently infected, and emaciation rapidly sets in. If the number of migratory trichinae is very great, death may be the result, though this is somewhat rare in the pig. Usually the different symptoms disappear gradually, and it is only in very debilitated animals that convalescence is slow. The presence of trichinae in the muscles does not appear to exert any subsequent influence on the development or fattening of the animals which harbour these strange creatures; on the contrary, it has been stated that they fatten more readily than before they were infected."—(FLEMMING'S Sanitary Science and Police.) The determining test, however, is the discovery of the parasites in the intestinal discharges, or in fragments of muscular tissue extracted by a harpoon.
The vitality of the trichines is not destroyed unless the
in which they are contained is exposed to the influence of
heat of boiling water for a sufficient time to insure that
every particle of it has been acted upon by that degree of heat. In
mere toasting of ham or bacon is insufficient to destroy the
worms, and smoked ham and German sausages are, unless well-
cooked, sources of danger. Many remedies have been sug-
getic for the destruction of the trichines in the treatment of the
disease, more particularly picric acid, picric-nitrate of potash
benzole, carbolic acid, sulpho-carbolute of soda, &c., but none of
these have been proved to have any effect; indeed, in trichins
pork of a pig killed with picric acid, the worms were found
alive by W. M"uller of Homburg.
CHAPTER LXXV.
PARASITIC DISEASES—continued.

TREMATODA.

ROT IN SHEEP.

Rot is a disease of low lands, marshy grounds, and wet seasons, and observers are agreed that the flooding of pastures suffices to taint them for a season, owing to the dissemination of the Distomata; for it is pretty satisfactorily proved that the ova of the fluke pass out through the intestines of the sheep, and fall on the pastures. The ova hatch in moist places, and become transformed into ciliated embryos, which, when set free, swim rapidly in the water, and thus spread over pastures in wet seasons.

Remarkable outbreaks of this disease have occurred in England. Professor Simonds, in his essay, records the outbreaks of 1809, 1816, 1824, 1830, 1853, and 1860. "In the outbreak of 1853-54 many thousands of sheep were swept away, and not only in undrained districts, but also in others of a more healthy character. But since 1830, however, no outbreak can at all be compared to the one of the autumn of 1860. Speaking in general terms, it may be affirmed that all the western and southern counties of England, together with several of the eastern and midland, suffered to a ruinous extent. As in former years so in this, the attacks of the disease were due to an excess and long continuance of wet weather. 1860 will long be remembered by agriculturists, not only as producing the rot among sheep, but likewise for its beneful effects on the root crops, as also on the hay and corn harvests." 1872 again was a wet year, and rot was very prevalent, appearing on land that was considered sound during ordinary seasons.
PARASITIC DISEASES.

In conjunction with the *Distemata* in the liver, it is an unusual thing to find other parasites infesting the bodies of the Strongyles in the abomasum, intestines, and lungs, cæcum, &c.—indeed symptoms similar to those of rot—are sometimes present independent of the fluke, and this circumstance has erroneously to conclude that the debilitated condition of the sheep renders it a favourable habitat for the parasite; in fact, the mal-condition induced by damp food is the cause of the disease and not the effect, hence it is termed watery cachexia *aqueosa*, by some writers.

It is important that this disease be distinguished in its early stages, and in order to enable the sheep-farmer to do this, the following rules are given by Mr. Beattie in the *Transactions of the Highland and Agricultural Society of Scotland*, vol. 1807:

"The first thing to be observed is in the spring, when they are dropping their lambs. A sound ewe in good order drops a lamb covered with a thick and yellow slime, which the ewe off it, and the rule is, the sounder and the higher condition ewe is in, the darker and thicker will be the slime; but when they observe a ewe drop a lamb covered with thin watery butter and very white, they note her down as unsound.

"About the month of September, when they intend to dispose of their draught ewes, they put all their sheep into a fold, and draw them by the hand; that is, they catch them all, viz. ewes they design to sell any of, and clapping their hand up the small of the back, they rub the flesh backwards and forwards betwixt their fingers and thumb and the ends of the short ribs. If the flesh is solid and firm, they consider her as sound; if they find it soft and flabby, and if, when they rub it agin the short ribs, it ripples, as we term it—that is, a sort of cracking is perceived—as if there was water or blubber in it, they are certain she is unsound. This is the most certain of all symptoms, but is not to be discerned with any degree of certainty but by an experienced hand; for although, as I have here stated it, it seems a very simple affair, and easily acquired, yet it is well known that many shepherds, who have followed sheep all their lives, never arrive at anything like certainty in judging by the hand, whilst men of superior skill will seldom be mistaken, and will draw by no other rule. Yet still it must be acce-
luded that the seeds of this disease will sometimes lie so occult as to baffle all skill, and that no man can, with absolute certainty, draw a flock tainted with the rot. There is another method, to which men of inferior skill resort, which is more easily acquired. They take the sheep’s head between their hands, and press down the eyelids; they thereby make the sheep turn its eyeball, so that they get a view of the vessels in which the eyeball rolls. If these are thin, red, and free of matter, they consider the sheep as sound; but if they are thick, of a dead white colour, and seem as if there was some white matter in them, they are confident she is rotten. This is a pretty general rule, and easily discerned; but I think it is not so certain as when they are judged by the back; for in firm heathy lands the eye of a sheep is far redder than it is in sheep upon grassy lands; and in some boggy lands, the eye is never very red, be the sheep ever so sound, so that there you cannot so well judge by the eye; but when you see the eye of a sheep a good deal whiter and thicker, and more matter in it (I mean the vessels in which the eyeball rolls) than the run of the flock amongst which it feeds, you have reason to suspect it is not sound."

In some instances the progress of the rot is very rapid, but usually it is slow and insidious. At first the affected animals appear to thrive very fast, but inactivity and dulness supervene; the mucous membranes become pallid, the flesh wastes, the general surface of the skin loses its ruddy colour, becomes dry and devoid of that oily condition which is natural to the fleece of the sheep. As the disease progresses, the flanks become hollow, the back rigid, weak and tender about the loins, as evinced by wincing when this part is pressed by the hand, and the spine sticks out prominently; the fleece drops off in patches, the belly enlarges, the eyes become yellow, and dropsical swellings appear in different parts of the body, particularly around the throat. There is often much thirst, depravity of the appetite, diarrhoea, general stupor, the pulse is weak, the heart’s action tumultuous, and anemic murmure are heard. As demonstrated by Delafond and others, the blood is deficient in albumen, thin, watery, and on this account the serum transudes through the walls of the vessels, collects in the loose areolar tissue of the depending parts of the body and in the cavities, constituting the condition of dropsy which is seen in rot.
Professor Simonds states that a dry scaly state of the skin on the inner parts of the thighs, particularly where it is unoccupied with either wool or hair, is early recognised, and that examination of the eye will materially assist in determining the question of disease. "If the lids are everted, the mucus nictitans being pressed forward, it will be found that in early stages of the malady, and especially if the animal has been excited by being driven a short distance, the vessels of the conjunctiva are tinged with a pale or yellowish-coloured blood, or that the whole part has a moist or watery appearance. In the same vessels are blanched, and scarcely to be recognised, excepting perhaps one or two, which present a similar condition, or are turgid with dark-coloured blood." In such cases these symptoms are complicated by others, induced by strongyles in the air passages and alimentary canal.

PATHOLOGICAL ANATOMY.

The tissues of the body are generally wasted, flabby, pale yellow, and watery; there is an absence of the firmness of the colour of healthy mutton. The peritoneal cavity contains a more or less abundant quantity of serum, which may be of a straw colour, or more or less yellow, in which occasion, fragments of lymph and false membranes are floating; if digestive organs are remarkably blanched; the liver is hard, scirrhous, irregularly knotted on its surface and margins, and sometimes united by false membranes to the surrounding organs. In colour it is either a dirty chocolate brown, deeper in some parts than others, or has a yellowish tint, intermixed with pale yellow spots. Flukes are found in the bile ducts, which are filled with a dark thick secretion; on further examination the ducts are found sacculated at various points, the distended portions generally containing many flukes massed together. The canal walls are much thickened in some places, and coated with calcareous matter on their internal surface. Professor Simonds mentions a case where a concretion was found as large as a hen's egg, which, when broken up, was found to contain about a dozen dead flukes. He also states that "the coats of the ductus hepaticus, as also of the ductus communis choledocius, are not unfrequently so thick as to be upwards of ten times their normal
substance, and likewise as hard as to approach the nature of cartilage."

Respecting the number of the flukes, the greatest variation exists. Dr Cobbold says—"The presence of a few flukes is totally insufficient to cause death; consequently, when a sheep dies from rot or is killed at a time when the disease has seriously impoverished the animal, then we are sure to find the organ occupied by many dozen, many score, or even several hundred flukes. Thus from a single liver Bidlow obtained 300, Leuwenhoek about 900, and Dupuy upwards of 1000 specimens. Even the occurrence of large numbers only destroys the animal by slow degrees, and possibly without producing much physical suffering, excepting perhaps in the later stages. Associated with the above described appearances, one not unfrequently finds a few flukes in the intestinal canal, whilst a still more interesting pathological feature is seen in the fact that the bile contained in the liver ducts is loaded with flukes' eggs. In some cases there cannot be less than tens or even hundreds of thousands. Not a few may also be found in the intestinal canal, and in the excreta about to be voided." And lastly, says the same author, "it need scarcely be added that it is by no means unfrequent to find one or even several other kinds of cestodes coexisting with the fasciola in the same sheep, the most common form being that of the larval echinococcus."

TREATMENT.

All observers agree that the growth and development of the fluke is impossible on dry land, and that the disease is unheard of on dry pastures except during wet seasons, and as the "rot," once established, is difficult to overcome, it behooves the flock-master to pay every attention to its prevention. For this purpose it is necessary that unsound sheep pastures should, after being drained, for a time at least, be applied to other purposes.

During moist seasons, and when there is a fear of the disease appearing on sound pastures, the natural food should be supplemented by cakes, corn, beans, or other nutritious diet, in addition to common salt and the sulphate of iron.

As to the beneficial effect of common salt, all writers are agreed that it prevents the development of the parasites, for it
is tolerably certain, as mentioned by Dr. Cobbald, that the larvae
of the Fasciola hepatica exists only in the bodies of fresh-water
snails and small aquatic animalcules. Seeing this is the case
and that salt marshes are exempt from the invasion of this
fasciola, would not the application of common salt to the lambs
be worthy of a trial.

For sheep that are actually affected but little can be done at
least in the way of a permanent cure. If the disease begins, its progress may be retarded, and the animals made fit for the
butcher, by removing them to a dry pasture, supplying them
liberally with food of a highly nutritious nature, and adminis-
tering salines and tonics.
CHAPTER LXXVI.

PARASITIC DISEASES—continued.

CESTODA.

The most important disease of stock caused by this order of parasites is that variously termed

STURDY, TURNSICK, OR CID.

This is a species of vertigo induced by the *Cœnurus cerebralis*, which is the hydatid or larval form of the tape-worm, called the *Taenia caenures*. Many conclusive experiments have been made in this and other countries, recorded in works on helminthology, which proves that the mature *Taenia caenures* infests the intestines of the dog, from which perfect segments are expelled. These segments, falling on the pastures where sheep are feeding, are swallowed along with the herbage, and, as explained by Dr. Cobbold, the six-hooked embryos, escaped from the ova contained in the segments, commence their wandering in the tissues of the higher animal, and, by virtue of their selective capacity, escape from the blood-vessels of the brain, and bore their way to their final resting-place in that organ. Even when the brain is reached, it by no means follows that every embryo attains its full growth. Indeed, it is only usual for one to flourish, sometimes two of equal size, but seldom more. It has, however, been observed that when one hydatid cyst has been removed, that another has developed in a different part of the brain. This proves that the brain serves as a proper habitat to one or at most to two hydatids at a time.

This disease attacks cattle as well as sheep, but in this country it seldom attacks any but sheep, its victims being lambs under
one year old, sheep above two years old being rarely affected. It prevails to a great extent on unenclosed lands, and for this reason that shepherds have to be assisted by dogs, while on enclosed pastures, and where sheep are unattended by dogs, the disease is scarcely known.

**Symptoms.**—The usual form of sturdy is that due to the presence of a hydatid in one of the cerebral hemispheres. The sheep affected, when caused to move, turns from right to left, or left to right, as the case may be; but when the parasite is lodged between the hemispheres, the animal staggers high, and goes forward in a straight line; the head is then carried upwards, and the may be a varying degree of amnesia in one or both eyes. Sometimes the animal becomes both blind and deaf, and is unable to follow its companions. When the hydatid is lodged in the cerebellum, the animal's movements are performed with little control. The head is elevated; the limbs are moved with difficulty and automatically; one or two steps are taken forward, when the animal starts with a bound, but immediately falls, is unable to rise for a time.

When the animal is first attacked, the symptoms are generally severe, from the congestion and irritation; as the contents of the skull adapt themselves to the hydatid, the brain symptoms become more or less; but as the parasite grows, the symptoms become more severe, until paralysis is induced, and the animal can no longer stand.

As many tumours and hydatids of different species are found in the brain which do not induce symptoms of sturdy, Darwin believes that the nervous substance is irritated by the heads of the parasites, which protrude from the bladder, and by means of their hooks and sucking discs penetrate the brain substance nearly two lines in depth. As the parasites grows, the animal becomes more and more emaciated, and death occurs, unless the sheep be relieved naturally or artificially. The natural method is by the bones of the skull becoming absorbed, the skin accidentally broken, and evacuation of the hydatid. This is, however, very rare.

The bones of the skull, however, are generally softened, and if in about three weeks after the first manifestation of the symptoms the head be pressed with the thumb, a remarkable degree of softening will be found at one part of it, as if the skull...
were wanting in that particular spot. Into this softened spot a trocar and cannula are introduced, and after the trocar is withdrawn—leaving in the cannula—a syringe is applied to the latter, and the bladder extracted.

"The prevention of the hydatid disease," says a writer in the Agricultural Gazette, "must begin at its source, and the first step is to expel the tape-worm from the intestines of the dog or dogs which are employed in the farm. It may be objected that this measure will be applied too late to remedy the mischief if the existence of the tape-worm is not suspected until some of the flock become affected with "gid;" but in fact the existence of tape-worm should always be suspected, and dogs should be treated periodically with areca nut as a measure of precaution. A dose of half a drachm to two drachms of the grated nut may be given now and then with safety, even when the tape-worm segments are observed, and if the remedy is not followed by the expulsion of a worm, the animal may be deemed secure. A second important means of prevention is to prevent the infection of dogs by destroying bladder worms immediately on their removal, instead of throwing them either to the dogs or in places where the animals can easily discover them. If this plan were universally adopted cystic entozoa would soon be diminished in number, and one source of loss to the stock-owner be averted. Sheep suffer from the entrance of embryos, which are expelled from the intestines of the dogs. Dogs become infested with the tape-worm in consequence of introduction into their digestive organs of the larval forms of the parasites, which exist in the brain of the sheep, being given to them, or placed within their reach. This interchange can be prevented by the exercise of a little common care.

"Sheep which are pastured on common lands, or fields through which a right of way exists, are exposed to risks of various kinds from which animals in isolated positions are exempt, and under such circumstances it is impossible to apply any effectual measures of prevention. In the case of "gid" some amount of danger is incurred from wild animals; foxes, for instance, may harbour the Taenia caecaris, and a few sheep may here and there become infested with bladder worms from eating the eggs expelled from the intestines of those animals, but these causes of infection are occasional and remote, and do not materially affect
the main question. Of the method of prevention, if the _larvarum_ were to be expelled from every dog in the country, effectually destroyed, the disease "gid," among sheep, would be very rare indeed.

"In reference to the treatment of the disease we have to urge. Puncture or removal of the cyst in many alleviates the distress which the animal suffers, but permanent cure is rare, and, knowing this, the farmer wisely consigns the animal to the butcher. He should, however, always beware for the return of the head, which contains the parasite, in the meat that he may buy, bury, or otherwise destroy it, and thus prevent thousands of embryos inert."

The various other diseases caused by _taenia_, in different stages of development, and other parasites, almost too numerous to mention, are not intended to be described in this work; helminthology being a specialty upon which many volumes have been written. In conjunction with this I may refer to a small work, namely, _The Internal Parasites of our Domestic Animals_, by Dr. Cobbold, as being the only book which deals exclusively with the entozoa of interest to the veterinarians. Under the able direction of Dr. Tommasi, an Italian, a work of this manual has been published at Florence.

I may, however, state that I have found an extract of the etherial extract of the male shield fern, to be the certain remedy for the expulsion of tape-worms, a table arrangement of which is given on the following page.

The drawings of the parasites have been mainly taken from Zurn, also from Heller, Krabbe, Leuckart, Cobbold, Kochmeister, and others.
Tabular Arrangement of Entozoa.

N. O. Nematoda.

Genus Ascaris.

(a.) A. megalocephala of horse and ass; found in the small intestine, occasionally passing from the duodenum to the gall ducts.

(b.) A. lumbricoides of man, pig, cattle; found in small intestine. The Ascaris of the pig is sometimes reckoned as a different species, viz., A. suilla.

(c.) A. mystax of cat and dog; rarely in man. Found in the small intestine. The Ascaris of the dog is sometimes reckoned as a different species, viz., A. marginata.

Genus Eustrongylus.

(a.) E. gigas of dog, horse, cattle, and very rarely man; found in the kidneys, bladder, and areolar tissue, beneath the peritoneum; sometimes free in the peritoneal cavity; also in the heart of the dog.

Genus Filaria.

Species (a.) F. lachrymalis of horse and ox; found in the lachrymal ducts.

(b.) F. papillosa of the horse, ox, and ass; found in the globe of the eye, said to be in the anterior chamber, but usually in a cyst within the cornea, also in the peritoneal and thoracic cavities, in the diaphragm and abdominal muscles, and in the arachnoid membrane of the brain.

(c.) F. immitis of the dog; found in heart, pulmonary arteries, and blood, hence spoken of as Hematozoa.

(d.) F. trispinulosa of the dog; found by Gescheidt in the capsule of the crystalline lens.

Genus Spiroptera (Filaria of some authors).

Species (a.) S. megastoma of the horse; found in tumours usually at the cardiac end, more rarely at the pyloric end of stomach; when these tumours are pressed pus and bundles of the worms are obtained. S. microstoma of the stomach of the horse is considered as a large variety of S. megastoma.

(b.) S. sangvinolista of the dog and wolf; found in tumours of the esophagus and stomach.
Species (c.) *S. strongyloides* of the pig, &c. ; found in the stomach.

(d.) *S. scutata oesophagae bovis* of ox, also described in the horse; found in the mucous membrane of the esophagus. Worms supposed to be the same are found in the stomach of pig and esophagus of sheep.

(e.) *S. hamulosa* of the common fowl.

(f.) *S. cincinnati* (*Onchoerca reticulata*) of horse; found in the sub-mucous layers of the wall of the alimentary canal.

**Genus Oxyuris.**

Species (a.) *O. curvula* of the horse and ass; found very frequently in the cecum and colon.

(b.) *O. vermicularis* of man; found in the large intestine and rectum.

**Genus Dibrachius (Strongylus of some authors).**

Species (a.) *D. hypostomus* of the sheep, goat, and other ruminants; found in the intestine.

(b.) *D. tubiformis* of the cat; found in the duodenum.

(c.) *D. trigonocephalus* of the dog; found in the stomach and small intestine. A variety is declared to exist in the right side of the heart.

(d.) *D. cervus* of sheep; found in small and large intestines.

(e.) *D. duodenalis* (*Anchylostoma duodenale*) of man; found in duodenum.

**Genus Strongylus.**

Species (a.) *S. armatus* of horse; sexually mature adults found in the cecum and colon, seldom in the duodenum, in the pancreas and tunica vaginalis of testis; the larval forms in aneurisms in the intestinal arteries; the eggs come out with the excreta and develop free living larval forms in water; the free living larvae get into alimentary canal with the water, and thence into the blood-vessels, where they cause aneurisms; becoming sexually mature they leave the aneurisms, and bore their way into the alimentary canal, where they copulate.

(b.) *S. tetragonatus* of horse; found in small intestine and cecum; the larval forms are free under the epithelium or enclosed in capsules in the mucous membrane of
the large intestine, where they attain sexual maturity, and then leave the mucous membrane and enter the alimentary canal. (Described at pages 723-25 of last edition as Trichonema arcuata.)

**Species**

(a.) *S. dentatus* of pig; found in large intestine.

(b.) *S. synagamus*, from the trachea and bronchial tubes of fowls.

(c.) *S. radiatus* of the ox, and several other ruminants.

From the small intestine and colon.

(d.) *S. venulosus* of the goat; found in the small intestine.

(e.) *S. micrurus* of cattle, horse, and ass; found in aneurysms of the arteries of the cow, and in the trachea and bronchial tubes. In the tough, yellow mucus of the air passages and bronchi they are to be found in countless numbers.

**Species**

(h.) *S. filaria* of sheep and goat, camel, &c.; found in the trachea, bronchial tubes, and lung-paranchyma. The ripe worms are coughed up and die. From the bodies of the dead females the embryos come forth. When they get into water they develop further, and live as free nematodes (or possibly as parasites on an intermediate host). These gain access to the stomach of the sheep with the water, wander into the lungs, and encyst in the parenchyma. When mature they leave the parenchyma for the bronchi. The forms described as *Nematoides ovis pulmonalis* are considered as embryos of *S. filaria*.

(i.) *S. paradoxus* of the pig; found in the trachea and bronchial tubes.

(j.) *S. filicollis* of the sheep; met with in the small intestine.

(k.) *S. ventricosus* of cattle; found in small intestine.

(l.) *S. intestinalis* of cattle, rare; found in colon.

(m.) *S. contortus* of sheep and goat; found in the abomasum, usually associated with *S. filaria*.

**Stephanurus dentatus** of pig; found in or about the kidneys. The kidney-worm of the Americans; Leuckart's *Sclerotoma pinguiscola*.

**Genus Trichina.**

**Species**

(a.) *T. spiralis*; sexually mature adults in alimentary canal producing living young, which bore their way into the muscles and encyst, forming the immature larval *T. spiralis* or Muscle Trichina; found in man, pig, ox, rabbit, rat, &c.
Genus Trichocephalus.

Species (a.) T. dispar of man.
   (b.) T. affinis of sheep and goat; rare in cattle; hind cecum.
   (c.) T. depressiculus of the dog; found in the cecum.
   (d.) T. crenatus of the pig and wild boar; found in the intestine.

N. O. Trematoda.

Genus Distoma (Euscelida of some authors).

(1.) Distoma hepaticum.—Leaf-like form, with a small sucker on the mouth, and a little behind this a ventral sucker, also a. Habitat, gall ducts and gall-bladder (usually only in spec. sheep, cattle, goat, and pig. Rarely in horse, ass, etc., very rare in man.
(2.) Distoma lanceolatum.—Lance-like form, with a tubular ventral sucker. Habitat, gall ducts and gall bladder of cattle, goat, pig. Wandering specimens also in blood and heart.
(3.) Distoma campanulatum, according to Ercolini, occurs in the of the dog.
(4.) Distoma conjunctum, found in the bile ducts of Indian dogs.
(5.) Distoma species have been found in muscles of pig, more particularly in the diaphragm.

Genus Amphistoma.

(1.) Amphistoma conicum, cone-shaped, thick posteriorly, with large sucker at the posterior end. Habitat, paunch of cat.
(2.) Amphistoma truncatum of cat.

Genus Hemistoma—Holostoma.

(1.) Hemistoma alatum of dog, wolf, and fox; found in small intestine.
(2.) Hemistoma cordatum of cat.

Genus Gastrodiscus.

(1.) Gastrodiscus polymastos, a disc-shaped trematode found in Sensino in Egyptian horses.

**Tania whose Cystic forms are unknown.**

1. Tania manu of man.
2. Tania expansa of ox, sheep, gazelle, chamois, &c.
3. Tania denticulae of ox.—France and Germany.
4. Tania pliata of small intestines and stomach of horses.
5. Tania manillae; large intestines of horse.
7. Tania elliptica of cat. Said by Van Beneden to be same as T. cynoecum.

(Fam. 2). Bothrioccephalidae or Pitheaded Tape-Worms.

Bothrioccephalus latum. Intestines of dog.
Bothrioccephalus cordatus.
Bothrioccephalus fusca
Bothrioccephalus reticulatula
Bothrioccephalus diopica
Not recognised in this country.
PLATE VII.

TAENIA CEREBRALIS.

Fig. 1.—Life History. Ovum, six-hooked embryo, 

Cestoda. 805

Fig. 1.—Life History. Ovum, six-hooked embryo, 

Cer. cerebralis (sheep), Taenia catus (dog).

Fig. 2.—Six-hooked embryo, surrounded by shell of ovum, highly

magnified. Notice shape of ovum; the shell consists of

layers, each layer composed of little prisms cemented

together.

Fig. 3.—The non-sexual cystic stage, Cer. cerebralis. Notice

the numerous heads or scolices with which the cyst is

provided; hence the name catus.

Fig. 4.—Head or scolex magnified 500 diameters. Notice restal-
lum and the crown of hooks, twenty-seven in number
(usually twenty-eight), arranged in two rings. Four oval

suckers, two being seen through the head. The calca-

reous particles are very numerous, and are often mis-
taken for ova.

Fig. 5.—Taenia catus : a shows the young anterior part of the

worm (natural size). A complete worm may have as

many as 230 segments. b and c show the segments as

they ripen. Observe how the uterus gains in conspi-
cuouslyness as the segments ripen. Notice also the genital

pore on the margin of each segment, and their alteration

in form as they become older. d. Segment magnified to

show the uterus.

TAENIA ECHINOCOCCUS.

Fig. 6.—The sexually mature taenia—a. natural size; b. magnified.

Notice the small size of the worm, the three segments, and

the head provided with hooks. G. p., genital pore.

TAENIA CUCUMERINA.

Fig. 7.—Head and segments of the sexually mature taenia.

a. Notice the protrusable restellum of the head. Only two of

the four suckers are seen (highly magnified).

b. Hook attached to the middle of a disc.

c. Four segments (natural size). Notice the rounded ends,
giving the segment the appearance of a cucumber; hence

the name cucumerina. Also that each segment is pro-

vided with a pair of genital pores (G. p.)

TAENIA MARGINATA.

Fig. 8.—a. The Cysticercus tenniocolis. Notice the round cyst, the

head evaginated, and the long thin neck; hence the name
tenniocolis. b, c. Notice the alteration in the

form of the segments. d. Head with suckers and hooks.

e. Segment magnified, showing uterus.
PLATE VIII

TENIA SERRATA.

Fig. 1.—a. Six-hooked embryo, surrounded by egg-shell.
   b. Cysticercus, with head evaginated, called piastra, from its pear-like form (nat. size).
   c. Part of the cysticercus magnified head invaginated, provided with suckers and hooks. Numerous calcareous particles are seen.
   d. Notice the saw-like margin of the segments, hence the name serrata.
   e. Shows how the old segments alter in form.
   f. Segment magnified to show the uterus.

TENIA SOLIUM.

Fig. 2.—a. Cysticercus with head protruding.
   b. Head magnified, showing the suckers and hooks.
   c. Ripe segment, magnified 6 diameters.

TENIA PERFOLIATA.

Fig. 3.—Observe the short but broad segments lying together, like the leaves of a book; hence the name perfoliata. Note the tapering posterior end, showing that it is a yolk-worm.

TENIA EXPANSA.

Fig. 4.—Observe that each segment is provided with two gonopores like T. cucumerina, but that the segments have quite a different form.

TENIA CRASSICOLIS.

Fig. 5.—Segment magnified.

BOTHROCEPHALUS LATISS.

Fig. 6.—Ovum highly magnified. Note the shape and observe the shell provided with a lid for the escape of the ciliated embryo.

Fig. 7.—The ciliated embryo, with a six-hooked embryo formed in its interior.

Fig. 8.—The six-hooked embryo casting off the ciliated coat.

Fig. 9.—The head. Observe (b.) one long groove or pit in the side of the head; the second groove not shown; (a.) artery of the head showing both grooves.

Fig. 10. Segment magnified to show the rosette-like uterus.

Fig. 11.—Shows the ventral genital pore. In a tape-worm the genital pore is marginal.
PLATE IX.

**Ascaris Megalocephala.**

Fig. 1, 2.—Male and female worms (nat. size).

**Ascaris Lumbricoides.**

Fig. 3.—Dissection of a female, with the parts laid out.

Fig. 4.—a, b. Head; c. Tail with spicules.

**Eustrongylus Gigal.**

Fig. 5.—The ovum; a shows the form of the shell and the markings on its surface; b. is a section of the ovum, showing the thick shell with the embryo coiled up in the interior.

Fig. 6.—a. Male worm (nat. size); b. Embryo worm.

**Ascaris Mystax.**

Fig. 7.—a. Natural size; b. Heart-shaped head (mag.)

**Oxyuris Vermicularis.**

Fig. 8.—a. Male (nat. size).

b. Female (nat. size).

c. Female (mag.) showing the internal organs.

d. Female (mag.) loaded with eggs, so that now the conspicuous part is the swollen uterus.

Fig. 9.—a. Ovum (mag.); b. Division has commenced; c. Embryo forming; d. Embryo emerging from the egg shell; e. Embryo free from the egg; f. Further advanced.

**Oxyuris Curvula.—**Fig. 10.

**Fertilization of Ascaris.**

Fig. 11.—a. Amoeboid spermatozoid.

b. Impregnation of the ovum.
PLATE X.

**Strongylus Tetracanthus,** formerly described as *Trichobilharzia ovata.*

Fig. 1.—Larva (slightly mag.) from mucous membrane of an Iceland pony. The worm was of a uniform rose colour.

Fig. 2.—Head (mag. 80 diameters).

**Parasites of Grouse Disease.**

Fig. 3.—The parasites embedded in the mucous membrane of the caecum (mag. 10 diameters).

**Strongyli from Bronchial Tissue of a Three-Year-Old Sheep.**

Fig. 4.—Magnified 80 diameters.

**Strongylus Filaria.**

Fig. 5.—From lung tissue of a sheep (mag. 80 diameters).

**Parasite from Liver of a Domestic Fowl.**

Fig. 6.—The fowl had been fed on the flesh of an Iceland pony infested with *Strongylus tetracanthus.* The whole of the abdominal visera of the fowl were covered with small tubercular-looking objects containing worms, embedded in a tough, almost cartilaginous substance (mag. 80 diameters).
Plate XI.

Filaria Papillosa.

Fig. 1.—Female (nat. size).
Fig. 2.—Male (nat. size). Notice the spirally wound tail.
Fig. 3.—Head (mag.)
Fig. 4.—Tail (mag.)

Strongylus filaria. (See Fig. 4, Plate IV.)

Fig. 5.—Female (nat. size).
Fig. 6.—Male (nat. size).
Fig. 7.—Head (mag.) Observe that the head is round, and provided with a round naked mouth.
Fig. 8.—Tail of male (mag.) Observe the bursa with the two spicules projecting from it.

Strongylus armatus.

Fig. 9.—The larva and sexually mature worm from the aneurism of a horse. The act of copulation is also shown; the small male is attached to the larger female by its bursa.
Fig. 10.—Shows the anatomy of the mature male and female.
Fig. 11.—The head. Observe the ring of teeth round the circular mouth.
Fig. 12.—The bursa. Notice the arrangement of the ribs.

Trichina spiralis.

Fig. 13.—Male worm from the alimentary canal of a man (mag.) Observe the pointed head and the round tail end provided with a pair of conical appendages for purposes of copulation.
Fig. 14.—Part of a female from the alimentary canal (mag.) Observe the young worms, some emerging from the sexual aperture, and others still in the interior.
Fig. 15.—Encysted trichinae in muscle (nat. size).
Fig. 16.—The same (slightly magnified).
Fig. 17.—Muscle trichina. Observe the spirally coiled worm in the interior of the cyst.

Trichoccephalus Affinis.

Fig. 18.—Observe the long, thin head end of the worm, hence the name Trichoccephalus.
PLATE XII.

LIFE HISTORY OF A TREMATODA.

Fig. 1.—Fertilised ovum, ciliated embryo, sporocyst, redia, cercaria (developed as an internal bud in the interior of a sporocyst or redia), encysted form, fluke.

OVUM OF DISTOMA HEPATICUM (mag.)

Fig. 2.—Observe the shell opening by a lid, and the embryo escaping through the opening.

CILIATED EMBRYO OF DISTOMA HEPATICUM.

Fig. 3.—Observe the cilia, the cross-like eye spot, and the large touch papilla projecting from the broad anterior end.

SPOROCYST (mag.)

Fig. 4.—Observe the ciliated coat cast off, the internal bud developing into cercariae, and the alimentary canal without an anus. A highly organised sporocyst, called a redia.

TAILED CERCARIA.—Fig. 5.

AMPHISTOMUM CONICUM.

Fig. 6.—Observe the conical form, the anterior and posterior suckers, the alimentary canal without an anus, and the ramified water vascular system.

ORGANISATION OF DISTOMUM LANCEOLATUM.

Fig. 7.—Observe the lanceolate form, oral sucker (O. S.), ventral sucker (V. S.), the bifurcating alimentary canal (A. C.), the testes (T.), uterus and female organs, and the water vascular system (W. V. S.).

DISTOMUM HEPATICUM.

Fig. 8. Natural size. Near the anterior end and the ventral sucker shown.

DIPTERA.

GASTROPHILUS EQUI.

Fig. 9.—Male and female (nat. size).

Fig. 10.—The larva or bot.

Fig. 11.—The pupa from which the fly has emerged.

Fig. 12.—Part of the stomach of a horse, with larvae (bots) lying in its interior.

TRACHEARIA.

PENTASTOMUM TERRICOLIS.

Fig. 13.—Internal organs.

PENTASTOMUM DSPERGICULATUM.—Fig. 14.
CHAPTER LXXVII.

BACTERIA.

BACTERIA, a division of the smallest and simplest of plants—rounded, ovoid, or spiral in shape—are unicellular and devoid of chlorophyll. They consist of protoplasam enclosed in a membrane, having a great affinity for certain stains, and are, in common with vegetable matters, not destroyed by potash, ammonia, or weak acids, and have the power of reproduction, some also of movement. They are divided into four great classes, each of which is recognised by the shape and size of its individuals, and also sometimes by their method of growth.

I. Sphero-bacterium, very small, rounded or ovoid in shape, and may be either micrococci or monada. If the latter, which are believed to be spores, they may be traced growing into tubules; if micrococci, the globular form remains.

II. Microbacterium, large rod-shaped, and may be bacteria or bacilli. If bacteria, they remain short; if bacilli, they may grow into lengthened filaments, having rounded cells—spores. These rods vary in shape; some are swollen in the middle, some pisoliform, swollen in the middle and attenuated at the ends; others constricted in the middle, as Bacterium termo; and some enlarged at one end—club-like. They are again divided into three groups—(a) coloured bacteria, found in ovine milk, &c.; (b) zymotic; and (c) pathogenic bacteria.

III. Desmobacterium.

IV. Spirobacterium.

Bacteria have been carefully measured, and the results are as follows:—

<table>

PLATE XIII.—BACTERIA, or SCHIZOMYCET

(Gr. schisma, a splitting.)

(Fig. 8 is after B caut, the rest after Dubit-Povr, based on Dr. Kchob's photogr.

Bacteria are those organisms which produce the change of organic as Putrefaction. Hay Bacteria, developed in an infusion of hay, may be examined first. Take some fresh hay, pour hot water upon it, and let it stand for the course of a day or two. The liquid becomes turbid, dust to it Bacteria, and latterly it has the smell of decaying vegetable matter. This liquid be examined under the highest power of the microscope, it contains Bacteria of simple form.

Figures X 8000, except Fig. 8.

Fig. 1. Microccoci (Gr. mikros, little; kokkos, a berry) are simply small oval cells, occurring free, or in chain-like rows, or in gelatinous mass. They are remarkable for the bright red color of the liquid in which they are tinged—red, blue, etc.

Microccoi prodigiosi—the blood-red Microcosmic form, appearing as blood-red, slimy drops, or in chains, or around the edge of the glass plate. From its appearance (often arising in the course of a single night) it has been superstitiously regarded as evil omens, as stories of "bleeding wafers" testify. The colouring matter is insoluble in water, but may be extracted by alcohol or ether.

Fig. 2. A chain of Microccoci found in putrefying blood.

The chain has probably originated from a single individual. The single cell lengthens as it grows, and forms a sort of figure of 8 preliminary to division, and this again and again would give rise to the chain.

Fig. 3. A gelatinous film or Zoogloea. This film or scum forms on the surface of putrefying and consists of a number of Microccoci embedded in a gelatinous material. This arrangement in rows has probably been induced, as in Fig. 2, by repeated division, as some are found in this condition.

Fig. 4. Bacteria (Gr. bakterion, a staff), or Cylindrical Forms—the rod-like bacilli are merely represented to show relative size.

These forms are the first found in the body after death, and are short or long rods, multiplying by transverse division.

Fig. 5. Rods from putrefying vegetable matter, with a vibratile cilium at each end, by means of which they wriggle about.

Fig. 6. Spirocheta (Gr. chiasis, hair). The spirochete is a spiral form, which is often revealed by the motion imparted to the bacillus by the blood corpuscles in the neighbourhood.

Fig. 7. Spirillum—to be found in puddles in summer where there is decaying vegetable matter.

They form inflexible spiral filaments, of one or several turns, and have a vibratile cilium at each end.

Fig. 8. Development of Spirillum—x 4.

(a.) Zoogloea-stage—motionless forms embedded in gelatinous material.

(b.) Vibrile-stage—bow-shaped forms passing into spiral forms.

(c.) Filamentous-stage—see the last elongated.

(d.) Filamentous-stage—further developed forms, in which the filament is long and motionless.

(e.) Filamentous-stage—spore-producing filament.

(f.) Filamentous-stage—ripe and motile filament.

(g.) Filamentous-stage—filament breaking up.

(h.) Spores which encyst and divide to form spore in the original Spirillum.

(i.) Spores germinating—little comma-shaped bodies which reproduce the original Spirillum.

Life History Diagram.—The stages are here given through which Spirillum passes in order to complete the cycle of its life.
FIG. 8.—DEVELOPMENT OF SPIRILLUM.

(a.) Filament producing spores.

(b.) Vibrio-like forms

(c.) Becoming filamentosus.

(d.) Motionless, well-developed filament.

(e.) Ripe motile filament.

FIG. 8a.—LIFE HISTORY DIAGRAM.

Spirillum.

Free spores encysting and dividing.

Spores germinating and dividing.

Zoogloss stage.

Vibrio stage.

Filamentosus stage.

Trocar in Flatulent Colic, 682
Tubal Sounds, 559
Tubercole, 406
Artificial Production of, 413
Causes of, 409
Chemical Composition of, 409
Conversion of, 408
Dr. Williams on, 410
Virchow on, 411
Symptoms of, 222
Treatment of, 424
Further Observations on, 417
Tubercular, Cheesy Matter not, 60
Deposits in Brain, 506
Dysentery, 419
Tumours, Cancers, 429
from Hypertrophy, 70
of Fissured Body, 507
Tympanitis, Causes of, in Horse, 648
in Ox and Sheep, Treatment of, 650
Symptoms in the Ox and Sheep, 649
Urea, Composition and Source of, 711
Demonstration of Nitrates of, 438
Influence of, in excess, 87
Nitrate of, 711
Oxalate of, 711
Source of, 87
Uric Acid, 712
Urines, Albumen in, 714
Changes in the, in Rinderpest, 159
Excess of Phosphates in, 714
Extraneous Matters of, 713
in Aetosuria, 438
in the Lower Animals, 710
in Oxaluria, 442
Incontinence of, 725
Pus or Blood in, 714
Retention of, 723
Saline Matters of, 713
Use of Thermometer, 44
Variation in Constituents in Blood, 72
Varicella Boil, 222
Varieties of Cough, 42
of Pulse, 35
Varicella Equine, 224
Varicella Orinis, 218
History of, 213
Post mortem of, 231
Statistics of, 221
Symptoms of, 216
Treatment of, 221
Vaccina, 205
Varicella Vaccina, Symptoms of, 205
Transmitted from Man to Cattle, 306
Treatment of, 212
Venous Pulse, 39
Transmissible, causing Rinderpest, 789
Trembling, or Leaping-ill, 522
Trichina Spiralis, 734
Trichinae, 739
Trichiniasis, 735
Trichodectes farinae, 738
Trichodectes latus, 732
Trichodectes levis, 735
Tricks of Horse-Coupers, 450
Tetranemat, 779
Trichinosis, 735
Trichiniasis, 733
Trichophalus Affinis, 740
Dispar, 738
Trichodectes levis, 732
Tricks of Horse-Coupers, 450
Triggers, 723
in the Ox, 405
Tinea, 186
Roaring, 556
Rot in Sheep, 703
Rupture of the Liver, 703
Scarlatina, 398
Spasms of the Diaphragm, 640
Spinis, 512
Superpurification, 654
Tapes-Worms, 798
Tubercle, 424
Tympanitis in Ruminants, 650
Varicella Orinis, 221
Varicella Vaccina, 212
Volvulus, 674
Trematodes, 742
Trembling, or Leaping-ill, 522
Trichinae, 733
Trichodectes levis, 732
Tricks of Horse-Coupers, 450
Tubercle, 406
